A choice that's right

for both of you.

- 29% lower progestin dose than 1/35.[1]
- Full-cycle breakthrough bleeding control equal to 1/35.[1]
- Unique "low-higher-low" phasing for extra mid-cycle protection.
- Norethindrone-based for low metabolic impact.[2,3]
- Supplied in the patient-preferred Wallette™ pill dispenser.[4]

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

P24,287

1. 1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. BTB comparisons are based on the first three cycles of use. Data available from Syntex Laboratories, Inc.
2. Wynn V, Niththyananthan R: The effect of progestins in combined oral contraceptives on serum lipids with special reference to high-density lipoproteins. *Am J Obstet Gynecol* 142:766-772, 1982.
3. Wynn V: Effect of duration of low-dose oral contraceptive administration on carbohydrate metabolism. *Am J Obstet Gynecol* 142:739-746, 1982.
4. In an independent survey the Wallette™ pill dispenser was preferred to the Ortho Dialpak by 7 out of 10 prospective OC patients. Data available from Syntex Laboratories, Inc.

TRI-NORINYL® TABLETS

(NORETHINDRONE AND ETHINYL ESTRADIOL)

Because your common goal is confidence.

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)
NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)
NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.
MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk.
B–Use associated with high risk.
C–Use associated with moderate risk.
D–Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy. Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease.* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences,* or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned.
Precautions *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings.
Adverse Reactions An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment); gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

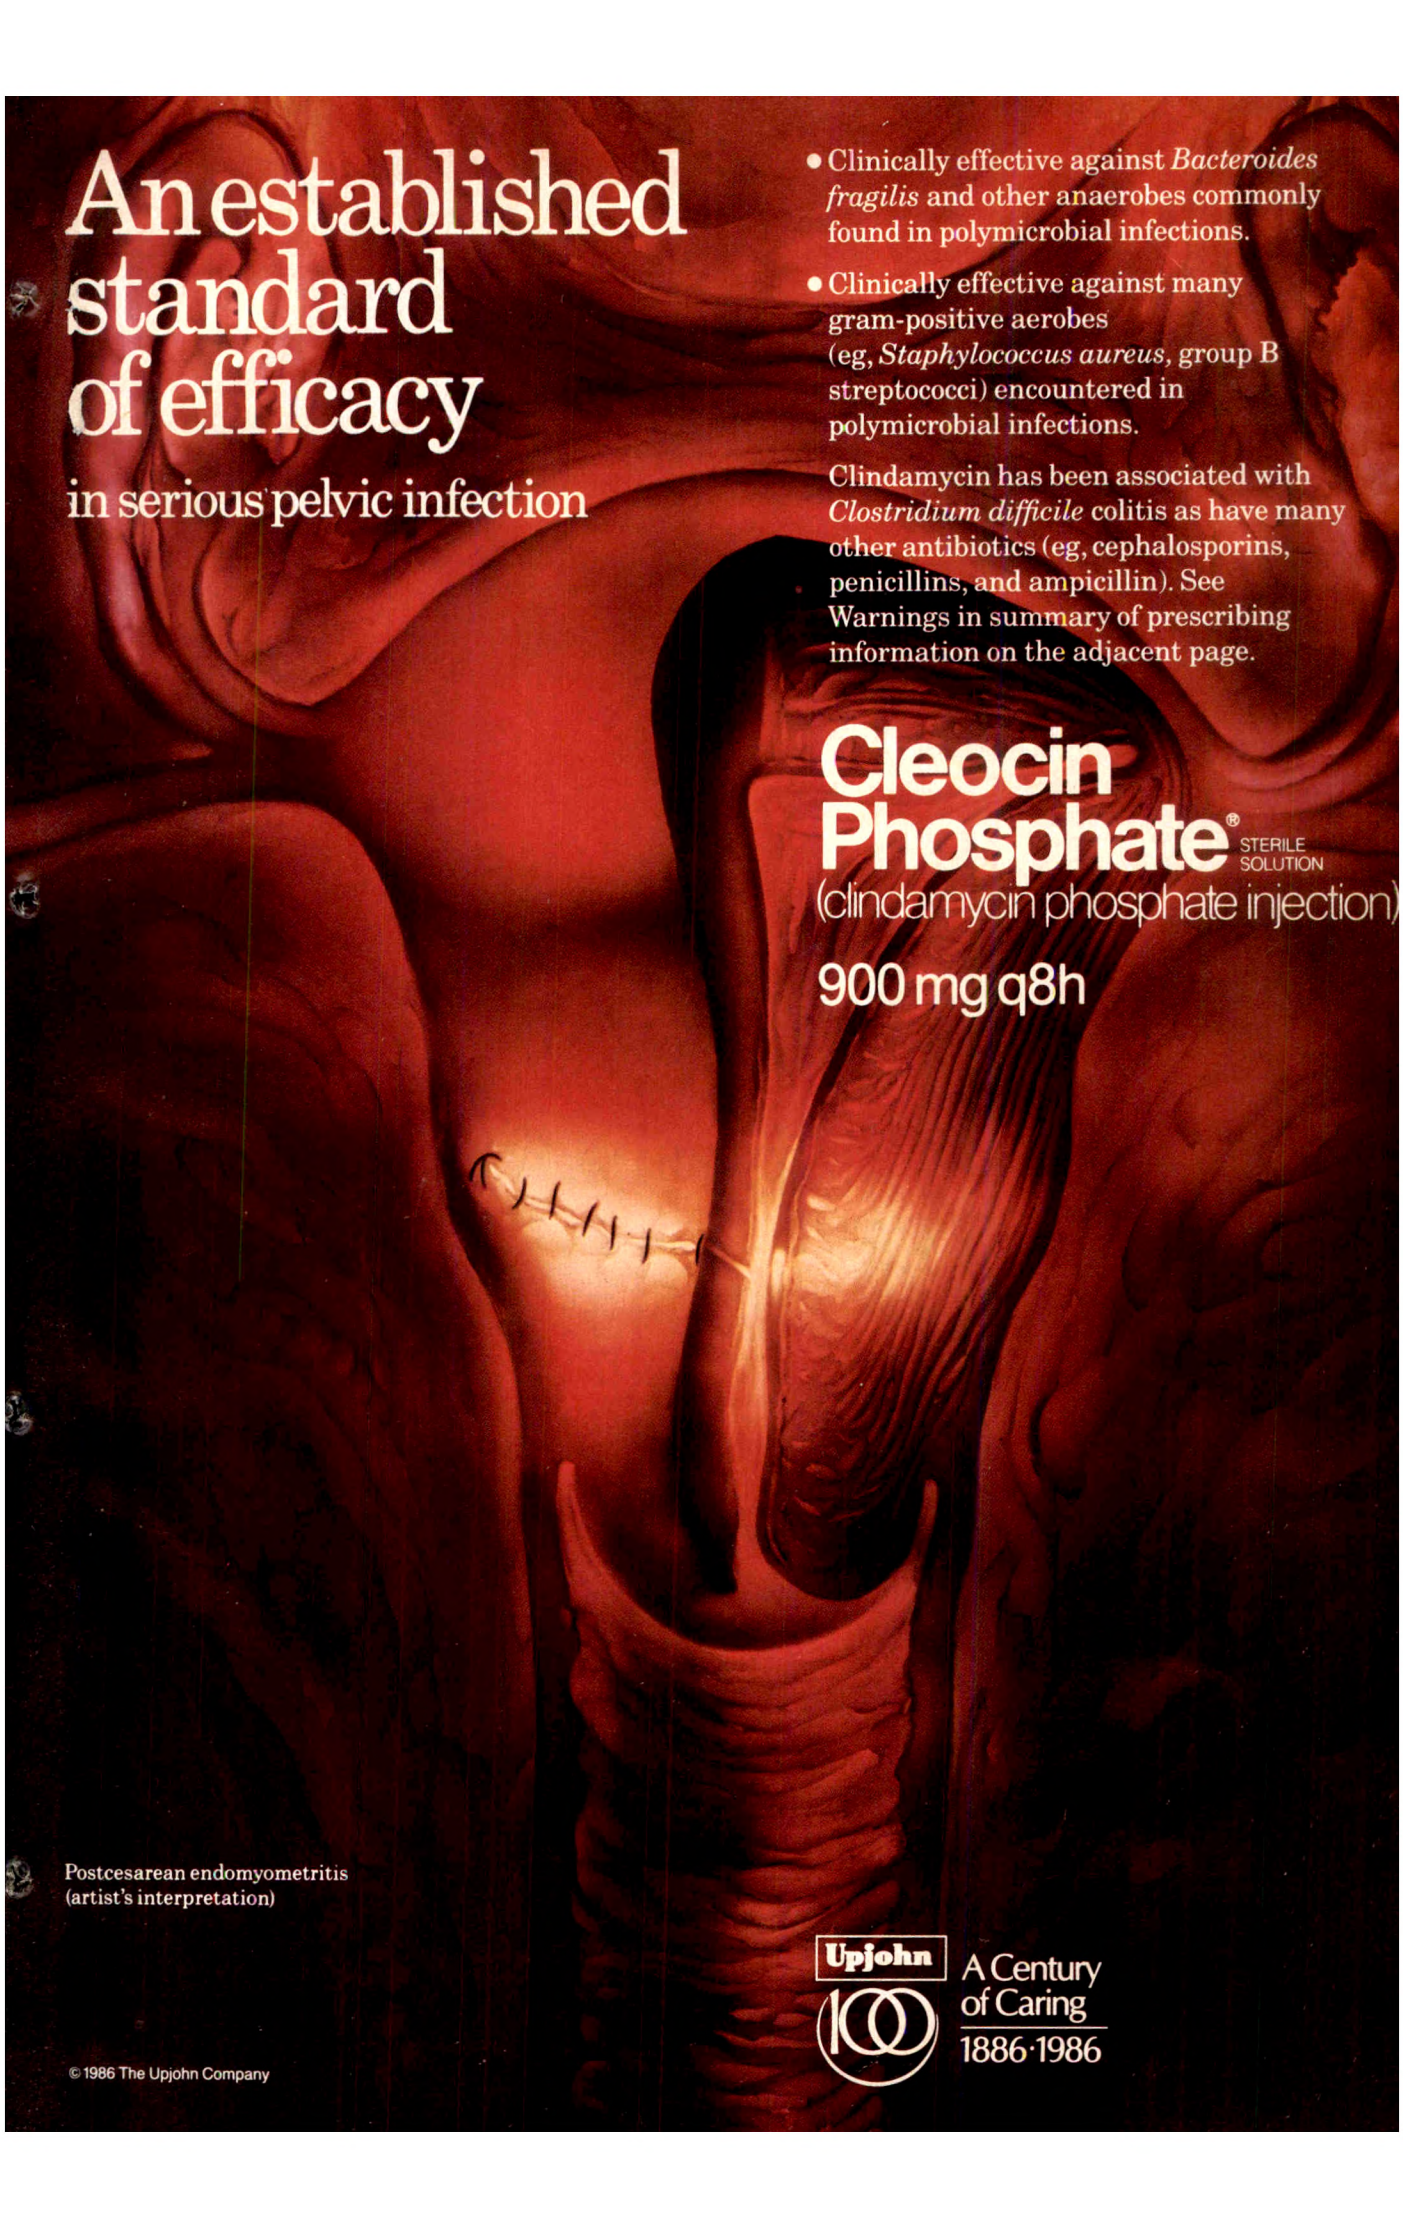
An established standard of efficacy

in serious pelvic infection



- Clinically effective against *Bacteroides fragilis* and other anaerobes commonly found in polymicrobial infections.
- Clinically effective against many gram-positive aerobes (eg, *Staphylococcus aureus*, group B streptococci) encountered in polymicrobial infections.

Clindamycin has been associated with *Clostridium difficile* colitis as have many other antibiotics (eg, cephalosporins, penicillins, and ampicillin). See Warnings in summary of prescribing information on the adjacent page.

Cleocin Phosphate® STERILE SOLUTION

(clindamycin phosphate injection)

900 mg q8h

Postcesarean endomyometritis (artist's interpretation)

CLEOCIN PHOSPHATE® Sterile Solution
CLEOCIN HCl® Capsules
(clindamycin)

WARNING

Clindamycin therapy has been associated with severe colitis which may end fatally. Therefore, it should be reserved for serious infections where less toxic antimicrobial agents are inappropriate, as described in the Indications Section. It should not be used in patients with nonbacterial infections, such as most upper respiratory tract infections. Studies indicate a toxin(s) produced by Clostridia is one primary cause of antibiotic associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro*. See WARNINGS section. The colitis is usually characterized by severe, persistent diarrhea and severe abdominal cramps and may be associated with the passage of blood and mucus. Endoscopic examination may reveal pseudomembranous colitis.

When significant diarrhea occurs, the drug should be discontinued or, if necessary, continued only with close observation of the patient. Large bowel endoscopy has been recommended.

Antiperistaltic agents such as opiates and diphenoxylate with atropine (Lomotil) may prolong and/or worsen the condition. Vancomycin has been found to be effective in the treatment of antibiotic associated pseudomembranous colitis produced by *Clostridium difficile*. The usual adult dose is 500 milligrams to 2 grams of vancomycin orally per day in three to four divided doses administered for 7 to 10 days. Cholestyramine or colestipol resins bind vancomycin *in vitro*. If both a resin and vancomycin are to be administered concurrently, it may be advisable to separate the time of administration of each drug.

Diarrhea, colitis, and pseudomembranous colitis have been observed to begin up to several weeks following cessation of therapy with clindamycin.

INDICATIONS

Serious infections caused by susceptible anaerobic bacteria. Patients with serious infections due to susceptible strains of streptococci, pneumococci, and staphylococci in whom its use should be reserved for penicillin-allergic patients or other patients for whom, in the judgment of the physician, a penicillin is inappropriate.

Consider the nature of the infection and the suitability of less toxic alternatives (e.g., erythromycin). Bacteriologic studies should be performed to determine the causative organisms and their susceptibility to clindamycin.

CONTRAINDICATIONS

History of hypersensitivity to clindamycin or lincomycin.

WARNINGS

See WARNING box. A toxin produced by Clostridia is one primary cause of antibiotic associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro*. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed promptly with fluid, electrolyte and protein supplementation as indicated. Vancomycin has been found to be effective in the treatment of antibiotic associated pseudomembranous colitis produced by *Clostridium difficile*. The usual adult dosage is 500 mg to 2 grams of vancomycin orally per day in 3 or 4 divided doses for 7 to 10 days. Systemic corticoids and corticoid retention enemas may help relieve the colitis. Other causes of colitis should also be considered.

A careful inquiry should be made concerning previous sensitivities to drugs and other allergens. Because antagonism has been demonstrated between clindamycin and erythromycin *in vitro*, these drugs should not be administered concurrently. *Usage in Pregnancy:* Safety has not been established. *Usage in Newborns and Infants:* Appropriate monitoring of organ system functions is desirable. *Nursing Mothers:* Clindamycin has been reported to appear in breast milk in ranges of 0.7 to 3.8 mcg/ml. *Usage in Meningitis:* Since clindamycin does not diffuse adequately into the cerebrospinal fluid, it should not be used to treat meningitis.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS

Older patients with associated severe illness may tolerate diarrhea less well. When clindamycin is indicated in these patients, they should be carefully monitored for change in bowel frequency. Prescribe with caution in individuals with a history of gastrointestinal disease, particularly colitis and also in atopic individuals. Indicated surgical procedures should be performed in conjunction with therapy. Patients with severe renal disease and/or very severe hepatic disease accompanied by severe metabolic aberrations should be dosed with caution and serum clindamycin levels monitored during high dose therapy.

During prolonged therapy, periodic liver and kidney function tests and blood counts should be performed. Use may result in overgrowth of nonsusceptible organisms, particularly yeasts. Clindamycin has neuromuscular blocking properties and may enhance other neuromuscular blocking agents. Use with caution in patients receiving such agents. Do not inject clindamycin IV undiluted as a bolus. Dilute prior to IV administration to 300 mg per 50 ml or more of diluent. Infuse over at least 10-60 minutes. (See Dosage and Administration.) CLEOCIN HCl Capsules contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS

Gastrointestinal: Abdominal pain, nausea, vomiting and diarrhea. (See WARNING box.)

Hypersensitivity Reactions: Maculopapular rash and urticaria. Generalized mild to moderate morbilliform-like skin rashes are the most frequent adverse reactions. Rare instances of erythema multiforme, some resembling Stevens-Johnson syndrome, have been reported. A few cases of anaphylactoid reactions have been reported. If a hypersensitivity reaction occurs, the drug should be discontinued. The usual agents should be available for emergency treatment. *Liver:* Jaundice and abnormalities in liver function tests have been observed. *Hematopoietic:* Neutropenia, eosinophilia, agranulocytosis and thrombocytopenia have been reported; no direct etiologic relationship to concurrent clindamycin therapy has been made. *Local Reactions:* Pain, induration and sterile abscess have been reported after intramuscular injection and thrombophlebitis after intravenous infusion. Reactions can be minimized or avoided by giving deep intramuscular injections and avoiding prolonged use of indwelling intravenous catheters. *Musculoskeletal:* Rare instances of polyarthritis have been reported. *Cardiovascular:* Rare instances of cardiopulmonary arrest and hypotension have been reported following too rapid IV infusion. (See Dosage and Administration.) *Renal:* Renal dysfunction has rarely been observed. No direct relationship has been established.

HOW SUPPLIED

Available as sterile solution with each ml containing clindamycin phosphate equivalent to 150 mg clindamycin base. Vials of 2 ml, 4 ml, and 6 ml.

CLEOCIN HCl as 75 mg and 150 mg capsules

Caution: Federal law prohibits dispensing without prescription.

For additional product information see your Upjohn representative.

For vulvovaginal candidiasis...
Mycelex®-G 500 mg
(clotrimazole)
Vaginal Tablet
MILES
In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended.

One tablet is the total treatment

See the following page for prescribing information.

MILES
Miles Pharmaceuticals

One tablet is the total treatment

Mycelex®-G 500 mg
(clotrimazole) Vaginal Tablet

INDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended. The diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis, *Trichomonas* and *Gardnerella (Haemophilus) vaginalis*, should be ruled out by appropriate laboratory methods.

CONTRAINDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are contraindicated in women who have shown hypersensitivity to any components of the preparation.

WARNINGS: None.

PRECAUTIONS: If there is a lack of response to Mycelex®-G 500 mg Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.

CARCINOGENESIS: No long term studies in animals have been performed to evaluate the carcinogenic potential of Mycelex®-G 500 mg Vaginal Tablets intravaginally. A long term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.

USAGE IN PREGNANCY: PREGNANCY CATEGORY B: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.

In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy.

Studies in pregnant rats given repeated intravaginal doses up to 100 mg/kg/day have revealed no evidence of harm to the fetus due to clotrimazole.

Repeated high oral doses of clotrimazole in rats and mice ranging from 50 to 120 mg/kg resulted in embryotoxicity (possibly secondary to maternal toxicity), impairment of mating, decreased litter size and number of viable young and decreased pup survival to weaning. However, clotrimazole was not teratogenic in mice, rabbits and rats at oral doses up to 200, 180 and 100 mg/kg, respectively. Oral absorption in the rat amounts to approximately 90% of the administered dose.

Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.

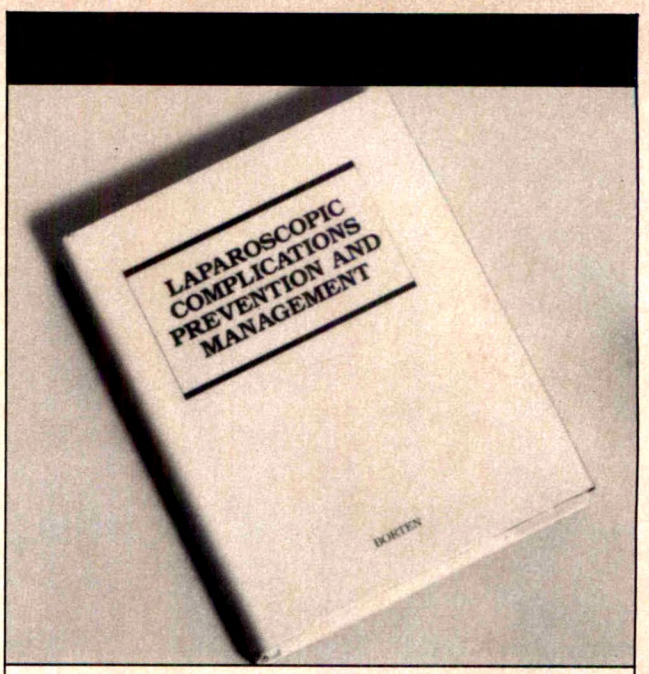
ADVERSE REACTIONS: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.

Eighteen (1.6%) of the 1116 patients treated with Mycelex®-G in other formulations in double-blind studies reported complaints during therapy that were possibly drug-related. Mild burning occurred in six patients while other complaints such as skin rash, itching, vulval irritation, lower abdominal cramps and bloating, slight cramping, slight urinary frequency, and burning or irritation in the sexual partner, occurred rarely.

OVERDOSAGE: No data available.

DRUG ABUSE AND DEPENDENCE: Drug abuse and dependence with Mycelex®-G 500 mg Vaginal Tablets has not been reported.

DOSAGE AND ADMINISTRATION: The recommended dose is one tablet inserted intravaginally one time only, preferably at bedtime. In the event of treatment failure, that is, persistence of signs and symptoms of vaginitis after five days, other pathogens commonly responsible for vaginitis should be ruled out before instituting another course of antimycotic therapy.



HOW SUPPLIED: Mycelex®-G 500 mg Vaginal Tablets are white, bullet shaped, uncoated tablets, coded with Miles on one side and 097 on the other, supplied as a single 500 mg tablet with plastic applicator and patient instructions.

LAPAROSCOPIC COMPLICATIONS: Prevention and Management

By Max Borten, M.D.

Written by a recognized authority, this book gives you first-hand knowledge on both medical and surgical management of laparoscopic complications. From indications and contraindications, it guides you through detailed discussions of failures of procedure and equipment, to the medicolegal aspects of both the procedure and its complications. Intraoperative slides and line drawings fully illustrate the text. Once you see it, you won't let it go! Order your copy today! April, 1986. Approx. 304 pages. (D-0723-X) Mosby distributes this B.C. Decker, Inc. publication. About $68.00

OUTLINE OF CONTENTS: INTRODUCTION: Instrumentation, Technique, Diagnostic Indications for Laparoscopy, Operative Indications for Laparoscopy, Laparoscopic Sterilization, Contraindications to Laparoscopy, Nongynecologic Indications for Laparoscopy, Choice of Anesthesia, Circulatory Changes, Respiratory Changes, Postoperative Recovery COMPLICATIONS: Equipment Failure, Procedural Failure, Complications of Anesthesia, Complications of Pneumoperitoneum, Complications of Trocar Insertion, Vascular Injuries, Intestinal Tract Injuries, Urinary Tract Injuries, Tegumentary Injuries, Complications due to Infection, Complications of Sterilization, Electrical Complications, Postoperative Complications, Medicolegal Aspects of Laparoscopy APPENDIX: Translaparoscopic Photography

LAST YEAR, WOMEN ALL OVER THE COUNTRY STOPPED USING THEIR CONTRACEPTIVE.

And started using ours. The Today® Contraceptive Sponge.

In fact, in the three years since The Sponge™ was introduced, over 50 million have been sold. And after just one year, The Sponge was the number one over the counter female contraceptive.

Women like The Sponge because it's comfortable, disposable and easy to use. And since it's non-interruptive, it never interferes with spontaneity. While it provides protection for a full 24 hours.

It's also safe and very effective. Clinical studies showed that The Sponge has an efficacy rate of 89-91% when used correctly. When not used consistently and correctly, effectiveness was 84-87%.

If you or your patients have any questions about The Sponge, call our Today Talkline at 800-223-2329 (in California 800-222-2329).

The Today Contraceptive Sponge. It could be your answer for patients looking for a safe, effective alternative.

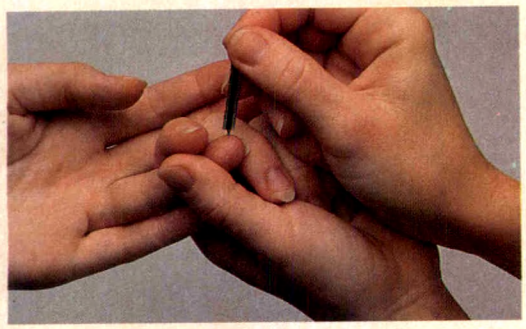
Hemoglobin determination, traditional procedures.

Traditional in-office Hb testing involves messy reagents, pipettes, test tubes, etc – not to mention instrument calibration and zero setting. A complex and time consuming procedure with high error potential, especially in the dispensing of blood and reagents.

Or take hematocrit where errors can arise from incorrect centrifuge speeds. And more to the point, why measure hematocrit when it is the Hb value that defines anemia?



And what if you use an outside laboratory instead? When the test results finally arrive the patient has long since left your office. The case record has to be extracted again, the patient contacted and perhaps recalled.

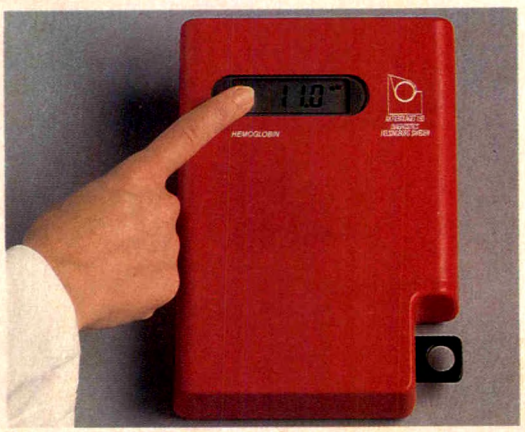
The new 60-second HemoCue procedure.



1. *Obtain a blood sample by finger stick.*

2. *The HemoCue microcuvette draws an exact amount of blood.*

3. *Insert the microcuvette into the HemoCue photometer.*

4. *Result displayed automatically within 15–45 seconds.*

The secret of the HemoCue Hb test system lies in the unique disposable microcuvette, which serves as pipette, test tube and measuring vessel in one. Containing a dry reagent it self-fills with blood by capillary action to produce a precise chemical reaction.

The HemoCue photometer is fully automated. The only control is the ON/OFF switch! No liquid reagents are used. Zero setting and functional adjustments are performed automatically between tests. It also automatically compensates for turbidity in the sample!

Thanks to HemoCue you can now get **accurate** Hb test results, truly stat, while the patient is still in your office.

For more information on this new and economical test, call 800-323-1674 (CA 714-859-7779).

Safe & Secure

The Surgicraft® Copeland

FETAL SCALP ELECTRODE

For greater safety and ease of application during birthing.

Specifically designed to instantly and continuously monitor fetal distress. Its exclusive design cannot be overscrewed, depth penetration is completely controlled, and trauma to the fetal scalp is reduced to a minimum.

- Expedient removal of the needle in the event the patient must be quickly moved from the labor room into OR theatre.
- Automatic control of the depth of needle penetration which remains guarded during insertion or removal.
- Protection against needle unscrewing or falling off.
- Available in disposable and re-usable models.

Patent Nos. 1.316.072. 1.523.263. 4151835 U.S., and others pending.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by The C. V. Mosby Company for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page is paid directly to CCC, 29 Congress St., Salem, MA 01970; phone (617)744-3350. TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

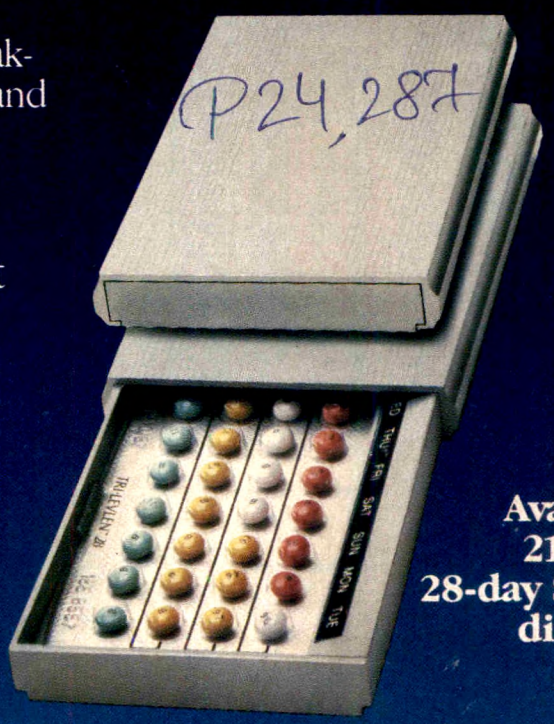
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should read and remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These data represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

Second to none for low total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Minimal impact on the following metabolic and hemodynamic parameters*



Lipids,[1-3] carbohydrate metabolism[1-3] and blood pressure[1] were not significantly affected in specific clinical studies.

Low incidence of breakthrough bleeding

A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

The confidence of 170 million cycles of experience worldwide

Available in 21-day and 28-day Slidecase™ dispensers

TRI·LEVLEN™21 TRI·LEVLEN™28

TRI·LEVLEN™ 21
TRI·LEVLEN™ 28

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3,17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000); the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if

applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the U.S. National Library of Medicine in *Cumulated Index Medicus*. Journal titles should also conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper. For black and white illustrations, submit three sets of 5 by 7 inch (8 by 10 inch maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

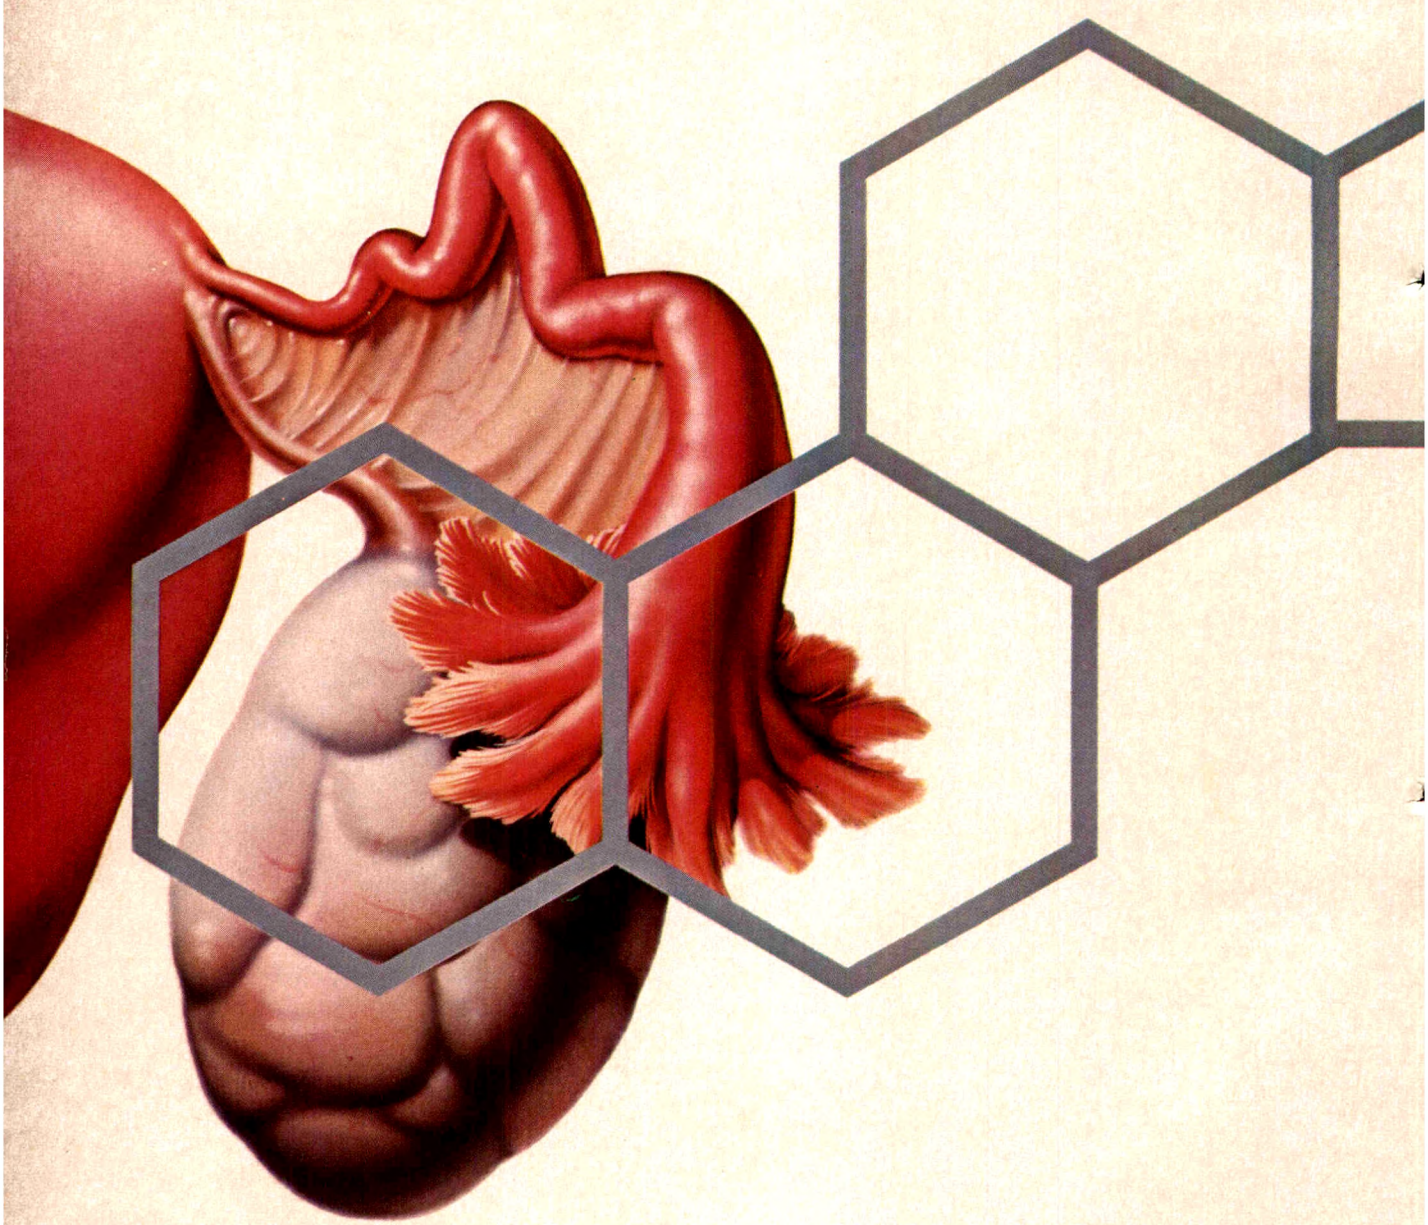
Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

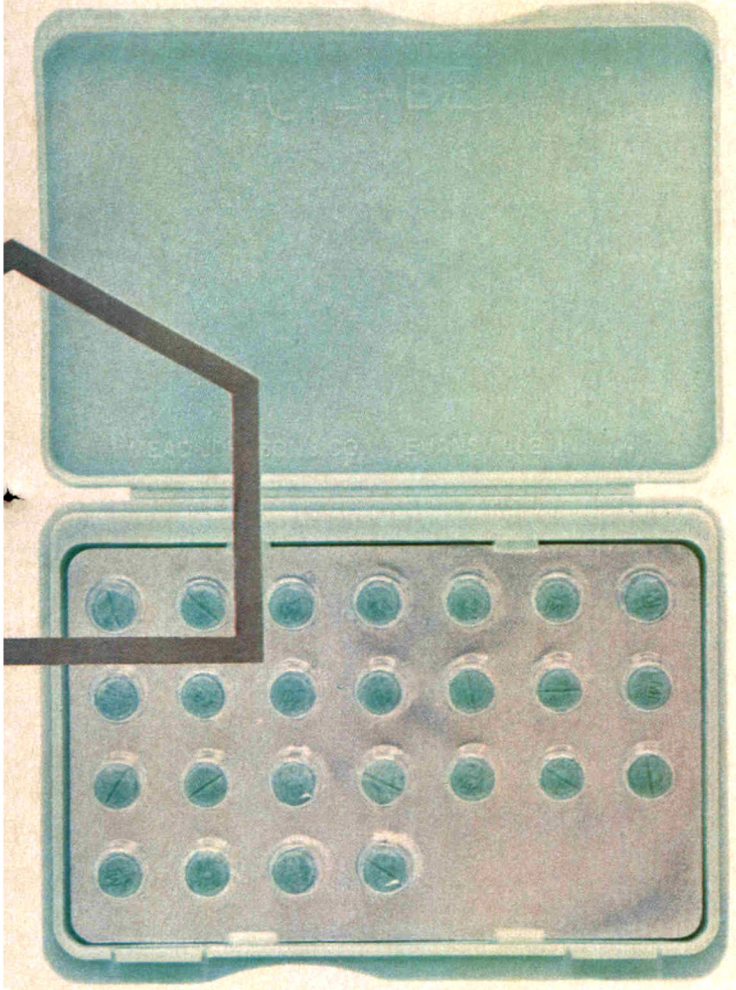


Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL— 17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Information for the Patient*—See text of Patient Package Insert. *Pregnancy Category X*—See Contraindications and Boxed Warning. *Nursing Mothers*—Administer to nursing mothers only when clearly necessary.

The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes. *For Prescribing Information, please see physician package insert.*

TRANSACTIONS OF THE FOURTH ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL AND OBSTETRICAL SOCIETY

Words, thoughts, and things

Presidential address

Joseph Seitchik, M.D.

San Antonio, Texas

I will take this opportunity to discuss two specific aspects of the relationship of our specialty to society. First, we will consider the words we use, presenting examples of how well they express or obscure our knowledge and our ignorance of some diseases and conditions we are expected to diagnose and treat. Second, we will identify changes in the practice of obstetrics in this century that represent responses by physicians to public criticism generated by women: most identified with or were sympathetic to the women's movement for social and economic equality. My observation is that physicians who practice obstetrics have always reacted to these pressures, that our responses were often inappropriate and accompanied by the appearance of new words and phrases, symbols that characteristically provided few clues to their precise meaning because they contained so little. In addition, I will present my views on the origins of the criticism and a few suggestions that I have the audacity to believe would reduce both the quantity and intensity of the complaints and aid in directing us toward appropriate responses.

"Words, Thoughts, and Things"; this is not original but is a chapter title borrowed from a book by Ogden and Richards[1] titled, *The Meaning of Meaning*. While reading literary criticism I found repeated references to it and my cowardly, but guilt-assuaging, response was always the same: "I'll save that one until I retire." I retired and, to my pleasure, I discovered that they were a pair of Cambridge University philosophers concerned with the problems created in communication between academics, because words used to express ideas are imprecise and suffer varying interpretations. When first published in 1923, their ideas must have been quite novel, for the book went through eight editions, the last in 1946.

Their proposition is simple: "Words as everyone now knows, 'mean' nothing by themselves . . . It is only when a thinker makes use of them that they stand for anything, or in one sense, have 'meaning.' " Take the word sequence: what shall we have for dinner mother. In your minds, place this phrase as a caption on a cartoon of a mother in a modern kitchen with a preadolescent child at her side. There is total coherence: in the words, the thoughts, and the things. Now if words have certain, precise, and explicit meaning, let us change the cartoon to a forest or jungle scene with a group of cannibals sitting around a very large pot over a fire. A head covered by a sunbonnet appears just above the edge of the pot, with the same caption, "What shall we have for dinner? Mother!" These are identical words in identical sequences but with totally different meanings.

According to Ogden and Richards,[1] the first step in separating the intellectual and emotive uses of language is to appreciate "the relationships of words, thoughts and things as they are found in cases of reflective speech uncomplicated by emotional, diplomatic, or other disturbances" (Fig. 1). Ogden and Richards use the word "referent" as we might use the word "thing," but because thing is usually used to denote material substances only, they adopted the word "referent," which stands for "thing, object, or entity." They teach that there is a strong relationship between things and

From the Department of Obstetrics and Gynecology, the University of Texas Health Science Center at San Antonio.

Presented at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.

Reprint requests: Joseph Seitchik, M.D., Department of Obstetrics and Gynecology, the University of Texas Health Science Center at San Antonio, 7703 Floyd Curl Dr., San Antonio, TX 78284.

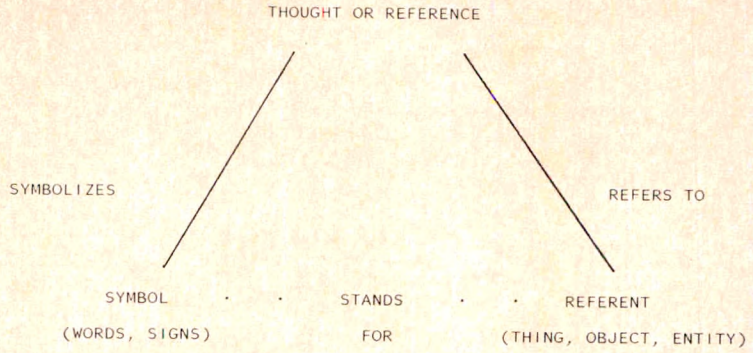

Fig. 1. The Ogden-Richards model of the relations of "words, thoughts, and things."

thoughts, referent and reference: causal relationships between words and thoughts, symbol and reference. But a word can only "stand for" an object; it cannot give meaning to it. They insist that if intellectual communication between humans is to be meaningful, we must differentiate between words, thoughts, and things. We must recognize that the emotive power of a single set of words and signs can generate dissimilar thoughts in different persons, which then produces inconstant referents. The result is that, except for a few onomatopoeic words, there is no cognitive association between words and things. An initial response to this whole proposition is, "it's obvious." Yet it is not. Think of the patient's response when the need for biopsy or colposcopy is announced. What causes her fear? Is it the phrase, "possibly malignant" (symbol), the idea of having cancer (reference), or the cancer itself (referent)? We recognize that it is not the disease she dreads, for the patient does not have the disease, the thing, the referent but suffers all of the terrible, anxious thoughts engendered by the symbol. This is one subject: how the interplay of words, thoughts, and things reflects the relationship of our specialty to society in general and to our clients, women, specifically.

Returning to *The Meaning of Meaning*, the book concludes with *Supplement II, The Importance of a Theory of Signs and a Critique of Language in the Study of Medicine,* by Crookshank. Crookshank was well known but unloved. After returning from service in France in World War I, he practiced in London, wrote a monograph on influenza (1922), which was well received by the profession, and started the Medical Society of Individual Psychology, which introduced Adlerian principles to the practice of psychiatry in England. He also wrote a dreadful book, titled *The Mongol in Our Midst,* presenting the preposterous hypothesis that the human race consists of several different species of different evolutionary origins. He graduated first in his class and was an accomplished debater who enjoyed bullying and embarrassing his opponents at public confrontations. His obituary in the *Lancet* reads, ". . . he displayed unusual erudition and a subtlety of argument which more than occasionally defeated its own purpose, requiring for its comprehension, a similar subtlety on the part of reader or audience. In argument consequently, Crookshank was too ready to blame the other side for failures to perceive what he had failed to explain . . .."[2] I hope that will not be the epilogue to my presentation today. Crookshank's complaints about physicians were twofold. First, he objected to physicians viewing diseases as entities in themselves as if they existed apart from the species *Homo sapiens.* Diseases must be viewed solely as pathologic processes with their manifestations in symptoms and signs. He argued that "diagnosis should mean the finding out of all that is wrong with a particular patient and why." He objected to the habit of the "formal and unctuous pronouncement of a name that is deemed appropriate and absolves from the necessity of further investigation." He wrote, "Medicine . . . has forfeited pretension to be deemed a Science because her Professors and Doctors decline to define fundamentals or to state first principles, and refuse to consider, in express terms, the relations between Things, Thoughts and Words involved in their communications to others."

This concept of the difference between thoughts and things was neither new nor unique to Cambridge dons. In Samuel Johnson's fable "Rasselas,"[3] the wise man, Imlac, attempts to educate Rasselas, an intelligent but young and inexperienced prince, to the difference between ideas and things. He says, "What space does the idea of a pyramid occupy more than the idea of a grain of corn?" William Carlos Williams,[4] general practitioner and poet, writes, "The poet does not . . . permit himself to go beyond the thought to be discovered in the context of that with which he is dealing: no ideas but in things." That was his battle cry, "no ideas but in things." The poet Wallace Stevens[5] wrote about ". . . that reality to which all of us are forever fleeing." This signifies that all intellectually serious and honest humans, not just philosophers and lexicographers and poets, must accept the responsibility to define reality with such clar-

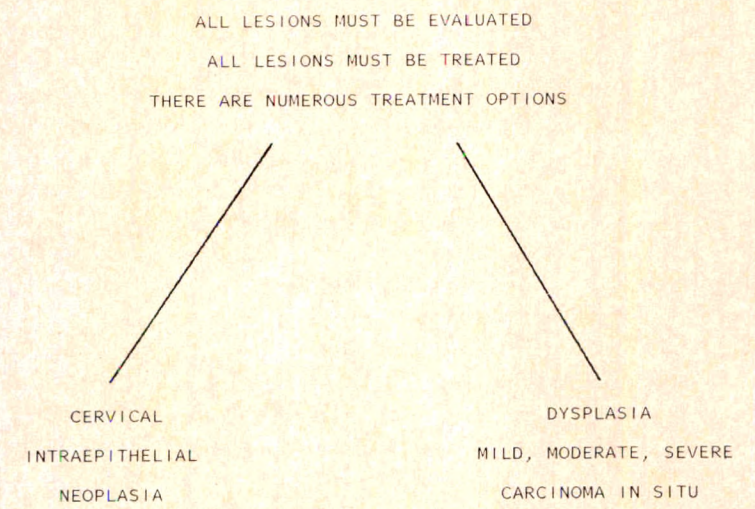

Fig. 3. Application of the Ogden-Richards model to the current view of preinvasive cervical epithelial lesions.

ity that our symbols evoke the same consciousness. It is my thesis that when we do, society is predisposed to accept our knowledge and leadership in health care. When we do not, we engender suspicion and hostility. I will give you a few examples, starting with a success.

With the recognition that epidermoid carcinoma of the cervix had a preinvasive phase called carcinoma in situ, physicians concerned with such problems provided words, thoughts, and things (Fig. 2). This formulation resulted in the performance of many hysterectomies and yet was accepted by society. We were praised for our efforts to identify and eradicate a major cause of death from malignancy in women. Yet that model was in part deficient and in part incorrect (Fig. 3).

What I wish to emphasize is that, as our knowledge of the lesion, the thing, expanded in both histopathologic and clinical dimensions, our words, the symbols, changed. Most important, the changes in language were consistent, not with the idea of the thing, but with the thing itself. As it was recognized that the lesion represented a histopathologic spectrum, including lesions that could regress spontaneously, cervical intraepithelial neoplasia replaced carcinoma, a change consistent with clinical realities. The words, thoughts, and things form a logical system. With all the complaints I hear and read about obstetrician/gynecologists, this is an area consistently avoided by our critics.

In contrast, the tripling of the cesarean rate in the 1970s resulted in the publication of many books critical of our practices and the formation of more than 30 lay organizations whose *raison d'être* is the protection of patients from our "unnecessary, aggressive practices."[6] If this increase in cesarean sections is beneficial to women and their neonates, we should be able to demonstrate the reality of the abnormalities that are the

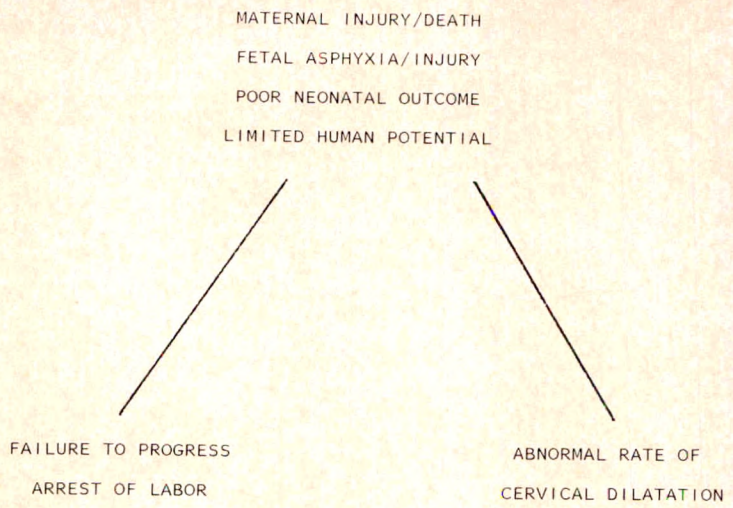

Fig. 4. Application of the Ogden-Richards model to the current view of functional dystocia.

causes for cesarean sections, the referent(s), the legitimacy of our thoughts, the reference(s), and the connotative specificity of the words we use, the symbols. Where shall we start?

Not in ideas but in things—what is the reality that resulted in the new ideas that produced more cesarean sections? Certainly no new obstetric disease has altered its occurrence from endemic to epidemic such as the venereal diseases—syphilis in the fifteenth century or acquired immune deficiency syndrome now. The specific anatomic dystocias such as contracted pelvis, brow presentation, and the like have decreased. The increase in cesarean sections is associated with the ascent of functional concepts of dystocia.[7] What happens when we apply the Ogden/Richards method of analysis to this problem? We start with the referent, abnormal rate of cervical dilatation and its symbols, failure to progress, and arrest of dilatation (Fig. 4).

If we are to be trusted, our words must reflect specific realities, not vague generalities. For those of us who experienced the great depression of the 1930s, "failure" was a frightening word with occasional suicidal sequence. After World War II, progress was our catchword. Economic progress would provide jobs for everyone. Progressive civil rights laws would assure equal opportunity for everyone. Thus "failure to progress" connoted something grave, something evil, when all it signified was some deviation from an average rate of cervical dilatation. The alternative phrase, arrest of labor, has a similar definition, but when used in a medical environment hints at associations with other arrests, cardiac for one. These are insinuating potentials for damage and death. The choice of these particular diagnostic symbols that reveal almost nothing, but have awesome, portentous connotations, should have aroused some suspicion that the phenomenon they purported to describe might be as ill-defined as the meaning of those phrases is delitescent.

Could it be that the words, the symbols, are poorly chosen but the events, the referents, all too real? How did we decide that episodes of no or slow cervical dilatation during labor are manifestations of pathologic processes rather than variants of normal processes? One standard, a minimum of 1 cm/hr and the need for action if the patient deviated from that rate for 2 hours, was developed as a rule of thumb for marginally trained midwives in Rhodesia to aid in identifying those patients who needed to be transported from their huts out in the bush to the hospital.[8] Other criteria for the definition of pathophysiology were developed as standard deviations from the means of the dilatation rates of large numbers of patients. What started out as a means of differentiating patients who were accomplishing their labor tasks rapidly from those less efficient and possibly in need of diagnostic reassessment became indications for special management techniques such as amniotomy, electronic monitoring, epidural anesthesia, and oxytocin therapy.

The severest criticism of the current cesarean rate is provided from three sources. Haverkamp et al.[9] challenge the need for monitoring and find that intermittent but frequent auscultation of the fetal heart rate suffices and that the elimination of electronic monitoring avoids escalation of the cesarean rate. O'Driscoll et al.[10] in Dublin insist that our high cesarean rate is unnecessary but substitute an aggressive system of care including a 40% incidence of oxytocin use in nulliparas. Finally, we have the newest feminist view of obstetrics.[11] To summarize their position, labor and delivery, although painful, can be a great source of pleasure, even with moments of ecstasy. Dealing with the pain is part of the business of being a woman who has chosen to

reproduce. Insecurity and anxiety make the pain worse; the support of an attentive father of the fetus and the assistance of a woman who has knowledge of the labor process are essential to success. These three systems of care are very different. One uses analgesics and anesthetics as required or requested; two do not. One insists that labor be rapid; two do not. One uses amniotomy and oxytocin frequently, one occasionally, and one not at all. All have similar cesarean rates on the order of 4% to 7%, depending on the mix of nulliparas and multiparas. They share only one common thread I can identify in their clinical practices. The common denominator is the continuous presence of bedside professional attendants.

Could the major cause of the increase in cesarean births from functional dystocia be so simple? Not that the monitor provides information that frightens the physician into inappropriate action as was once suspected but is now known to be untrue? Rather, these observations suggest that it is the absence of human support rather than the presence of the machine that is the villain. Whether my hypothesis concerning the mechanism whereby the new style of practice in labor and delivery increased the cesarean rate is correct is unimportant. What matters is that we cannot define a referent but only new thoughts that have increased the cesarean rate. What are these thoughts? Essentially they include that the increased cesarean rate will result in a reduction in perinatal deaths and that more cesarean births will produce more live and healthier neonates. What is the referent for these new practice ideas if they were not based on specific obstetric diseases? It is my thought that this change in practice was a response to public criticism, specifically to the complaint that the perinatal mortality rate in the United States was considerably higher than in several European countries. This habit of change in obstetric practice in response to public pressure has been and is typical of obstetric care in the United States in the twentieth century rather than extraordinary. Obviously, the events to which I refer are not those life-saving therapies designed for the treatment of specific disease entities—cesarean delivery for placenta previa, tracheal intubation for the prevention of meconium aspiration, or antibiotics for puerperal sepsis. No, I am referring to those styles of practice each of which, in its time, resulted from public pressure, each incorporated into obstetric practice, each eventually achieving public condemnation. I will review the evidence.

In the first decade of the twentieth century, German physicians introduced scopolamine and morphine as combination hypnotic/analgesic therapy for the avoidance of memory of the pain of labor. By 1914 to 1915, this method of pain relief was not widely used in the United States. Why not? Its decreased use was probably due in part to its complications, in part because most deliveries occurred at home and most patients could not afford the professional attention this treatment required, or perhaps most doctors were simply ignorant; we do not know. Mrs. C. Temple Emmet of New York, a granddaughter of the Astors, delivered in Freiburg, Germany, in 1909, experienced "twilight sleep," returned there for a repeat performance twice more, and, with her friends, initiated the National Twilight Sleep Association in New York City in 1915. This was a movement generated by upper-class club women and female physicians, for example, from Boston, Mrs. Jesse F. Attwater, editor of a magazine, *Femina,* and Dr. Eliza Taylor Ransom, physician and women's rights activist; from New York, Rheta Childe Dorr, author, suffragist, and trade unionist; and from Chicago, Dr. Bertha Van Hoosen, physician. None of these women is identified as general feminists, that is, leaders who recognized their gender as the basis for women's problems.[12] They were pragmatic feminists who identified specific areas of concern, such as the right to vote and exploitation of women and children in the workplace. It was not the radical feminists who concerned themselves with this issue, not the anarchists and socialists. It was upper-class women, in both wealth and education, who organized support for "twilight sleep." In the years 1914 to 1915, a series of articles appeared in the leading magazines of those days—*McClure's, Woman's Home Companion,* and *Good Housekeeping*—chastizing physicians for failing to provide twilight sleep to their suffering patients.[13a, 13b] These authors, Margaurite Tracy, Constance Leupp, Mary Boyd, and Hanna Ver Beck, were vigorous feminists seeking equal rights for women. They viewed twilight sleep as a means to equality. If women, like men, could avoid suffering the pain, agony, and terror of labor and delivery, one large difference in the experience of the sexes was deleted. The article in the *Ladies Home Journal* was accompanied by opinions the editors had requested from "eminent obstetricians." They were J. Whitridge Williams of Johns Hopkins, Charles M. Green of Harvard, Barton Cooke Hirst of the University of Pennsylvania, and Joseph B. DeLee of Northwestern University. All four condemned the use of twilight sleep. Nonetheless, under these pressures, physicians adopted twilight sleep. The effects were obvious: more hospitalization for delivery, but only for those who could afford it or the poor, an increasing role for physicians in the birth process, and a diminished role for the patient in her care. Physicians responded to this demand even though the deleterious effects of twilight sleep in slowing labor and inhibiting respiration in the newborn infant were obvious to those "eminent obstetricians" who had examined its effects objectively. We should not view this episode as a desire for women to seek less control of the childbirth expe-

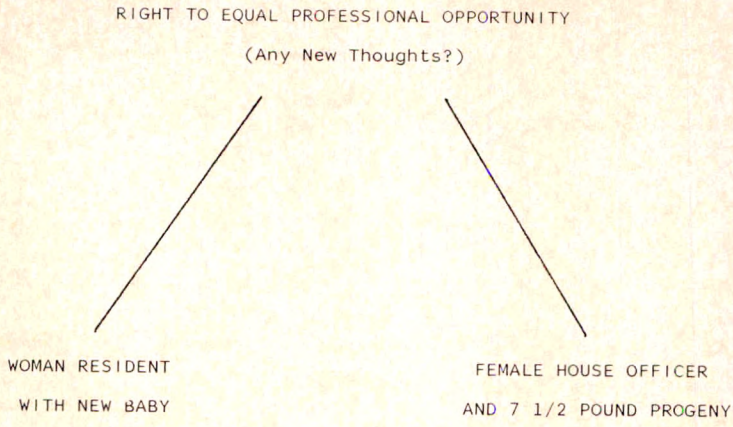

Fig. 5. A derisive and incomplete application of the Ogden-Richards model to maternity in residents.

rience. These women wanted more control. The fact that the "control" resulted in their amnesia is of no significance. They wanted to labor and deliver by a method of their choice.

Shortly after this outcry and response, another major innovation occurred in obstetric practice. By the end of the second decade, Dr. Joseph B. DeLee had introduced his system of care for all laboring women,[14] including normal obstetric patients without complications. In essence, it was an exercise in applying the methods of surgery to obstetrics. All patients had the genital areas shaved, all patients were draped in sterile vestments, all patients were scrubbed with antiseptics, all patients underwent a routine episiotomy, and all babies were delivered with routine low forceps. The goal of this system was not the treatment of any specific disease but an attempt to reduce maternal injury and death by the application of the principles of surgery to obstetric delivery in a hospital environment. Who was concerned with the maternal mortality rate? Not only were Dr. DeLee and his obstetric colleagues concerned but also Dr. Grace L. Meigs.[15] Dr. Meigs received her A.B. degree from Bryn Mawr College in 1903 and her M.D. degree from Rush Medical College of the University of Chicago in 1908. After interning at Cook County Hospital, she practiced in Chicago until 1914, when she moved to Washington, D.C. to become the Director of the Division of Hygiene of the Children's Bureau of the Department of Labor. In 1917, she produced the first official survey of maternal mortality rates in the United States, discovering that for women aged 15 to 44 years, maternity was the leading cause of death after tuberculosis. In a comparison with 15 other countries, including such different places as New Zealand and Spain, none had as many maternal deaths per 1000 live births as we. It is important to note that the language used by Dr. Meigs to identify the causes of this high maternal mortality rate was almost identical to that of J. Whitridge Williams.[16] To paraphrase them both: The problems were twofold: (1) Skilled obstetric care was not valued, so obstetric fees were very small; (2) physicians were also reluctant to assume the responsibilities of obstetric care because they were so often required to accept difficult cases of labor outside hospitals and without any nursing assistance. I must digress for a moment to contrast the situation as they described and recorded it at that time with the history of obstetrics in the United States, which is so popular with our academic critics from the humanities. In his book *Power and the Profession of Obstetrics*, William Ray Arney,[17] after assuring us of his objectivity and his recognition that there are two histories of obstetrics, one by us and another by our critics, he writes, "It (his book) uses the historical archive of the profession to examine the problems of, first, how the profession seized childbirth and staked it out as the exclusive domain of a new profession; . . .." First, note the word choices, "seized childbirth" and "staked it out." Surely this is language more suited to war or revolution than a description of evolutionary events occurring over a period of 2 centuries. Further, if the description relates specifically to the turn of the century in the United States, the writings of Dr. Meigs from the Labor Department and Dr. Williams at that time clearly indicate avoidance of obstetric cases by the vast majority of physicians—hardly "seizing" and "staking out."

The response to Dr. Meig's work seems limited to the specialty of obstetrics. I could find no newspaper or magazine article concerned with any aspect of maternal deaths in the year 1917. No editorial appeared in the *Journal of the American Medical Association*. The *New York Times* had many reports on women and war work, the suffragettes, and even on the women's peace movement but none on maternal mortality in the year 1917. The matter was not ignored by obstetricians. Dr. Meigs[18] addressed the New York Academy of Medicine, Section on Obstetrics and Gynecology, by invitation, on May 22, 1917. The transactions of the meeting were pub-

lished in the *American Journal of Obstetrics and Diseases of Women and Children,* and an editorial followed.[19] All the discussants agreed with the importance of her work and the need for action. The editorial is interesting in several respects. In analyzing the relative failure to reduce the number of maternal deaths during a period of relative success in reducing death rates from tuberculosis, typhoid, and diphtheria, the author writes ". . . the problem is vastly different . . . when one takes into consideration the numerous social and economic, in addition to the purely medical phases involved." The editorial paraphrases the various solutions suggested by "competent medical observers." They are: (1) improved teaching of obstetrics to physicians; (2) proper instruction and supervision of midwives; (3) adequate prenatal care and hospital facilities, particularly for women of moderate means; and (4) state grants of money to mothers of families who may require such aid. This does not seem to me to be a battle cry for the medical profession to "colonize childbirth." That quote, "colonize childbirth," is from the work of one of our English critics, Ann Oakley,[20, 21] who has authored *Women Confined: Toward a Sociology of Childbirth* and *The Captured Womb: A History of the Medical Care of Pregnant Women.*

Returning to Dr. DeLee's attempts to improve obstetric outcome by the application of surgical techniques to delivery, I cannot be certain that this was a response to the reality of Dr. Meig's data—the fact that maternal mortality rates had not declined from 1900 to 1913. Whatever his motivations, the truth is that Dr. DeLee's good intentions accomplished little in reducing maternal mortality rates. Abrupt decreases in maternal death rates have occurred only in association with new developments in medical science. The first major decline occurred in the 1930s in association with the general use of blood banking and the sulfonamides and the second following the availability of penicillin and blood products immediately after World War II. The maternal death rate remained almost constant from the time of Meig's report in 1917 to 1932 at 65 to 70 per 10,000 births, or approximately one maternal death per 150 deliveries.

If one were to look at the four decades from 1910 to 1950 and ask, "What can we learn from that period of obstetric history?" I would reply that it demonstrated that the best interests of maternity patients were served when our best current knowledge of medical science was applied in obstetric care. Further, it teaches that, at any singular time, our knowledge of medical science is finite. Significant new developments necessary to solve our patients' problems will come in their time but are not at our mere beck and call. When faced with a public challenge, we have responded by extending the application of the medical tools available to us without applying the scientific method to the analysis of their potential costs and benefits. This is our "as if" response. When criticized, we have sought responses to these challenges in terms of inadequately tested hypotheses or techniques. "As if" depriving mothers of any memory of childbirth, both the pleasures and the pain, will make women social and economic equals of men. "As if" applying the techniques appropriate to the surgical amphitheater is advantageous for laboring women. What this history teaches us is that every time these critical Eves have offered us a bite of the apple of complaint, we have gorged ourselves on all the fruits of technology. Some of our modern critics insist that we and our predecessors initiated the use of these therapies because progressive reliance on the physician to control the circumstances of birth assured physicians financial benefit. I deny that but would also insist that our responses have not been invariably consistent with the best health interests of our obstetric patients. It is a wonderment to me why we have not invested in understanding these public pressures and identifying and appreciating their origins instead of reflex responses that use medical technologies of uncertain value or safety. This pattern of reflex technologic response continues. We are now completing our most recent cycle. Having responded to the criticism of the 1960s, we increased the cesarean birth rate "as if" that would cause significant improvement in the quality and numbers of live-born infants—another response to public pressure in the enhanced use of medical technology without a clear, objective demonstration of its value. These events were followed by increasing criticism of this behavior from the public and government. Now clinical evidence indicates that recent cesarean rates were excessive, and I suspect that the numbers of cesarean births are declining. The cycle nears completion.

Could we eliminate this criticism if all our practices were scaled thoroughly by application of the scientific method before use? I think not, because the problem is rooted in biology. If, by some miracle, we should change our history and provide women with every equal right in every area of human endeavor, the one remaining, intractable difference between men and women would be pregnancy and the labor/delivery experience. If nature provides us with this difference between males and females in the production of the neonate, what are the legitimate derivatives in nurture?

Can Ogden and Richards help us? Let us start with a simple example. The referent is a female house officer. The symbol is a woman physician, and I believe that, on all teaching services today, the thoughts are of equality: equal opportunity for education and training and practice or academic career. Now let us complicate the diagram (Fig. 5).

Are there any new thoughts? I believe there are. Until

1981 neither the Residency Review Committee nor the American Board of Obstetrics and Gynecology found it necessary to provide a national standard for sick leave and vacations. I presume these organizations thought such matters were best managed at a local level with the director of the residency program making these judgments. But in 1981 a new rule appeared in the American Board of Obstetrics and Gynecology bulletin, limiting total absence for nonprofessional activities to 6 weeks per year. Greater absence requires compensatory makeup time. I have struggled to identify the recent epidemic of disease among obstetric and gynecologic residents that has stimulated this new regulation but can find none. Perhaps it is unfair to relate this action to the fact that women physicians are or soon will be a majority among our residents. But the history of women is so rife with these examples of loss of equality on childbirth, it is difficult for me to avoid suspecting this cause-and-effect relationship.

While the seed of the problem is in nature, how it germinates and what the seed produces is in nurture. How will the "equality" of our reference be maintained if the problem of childrearing is the mother's major responsibility? There is no way she can avoid constriction of her educational opportunities and eventually diminished career and income. Would it not have been a great symbolic leap forward, promoting mental health and equality, if the Residency Review Committee and American Board of Obstetrics and Gynecology issued a statement that read like this: "Because only women have the unique capacity to produce new humans, an ability we value as a society, every effort should be made to assist those female residents who decide to help renew the human race by having children during their residencies. We recommend that every hospital establish 24-hour nurseries for the residents' children so that they may return to work as soon as possible and can continue to nurse. We believe nursing is important to the health of these babies."

This paradigm is a small example of a very important issue: How do we compensate for the career limits placed on women because of the arrival of children or how do we avoid these limits? We have an enormous range of opinion.[22] Some think this is a responsibility of the nuclear family. Others think that society must invest in maintaining equal opportunity for women post partum, particularly in these days of more nuclear family fission than fusion. Others believe that women will be able to have children without loss of their personhood only when men change their orientation to acceptance of equal responsibility for child rearing. What is the relationship of all this to our critics?

While it may seem bizarre, examination of the bulk of these publications reveals that the majority of our critics are women who have resolved this particular problem. The "twilight sleep" movement was led by club women so wealthy that some not only went to Freiburg to have their babies but stayed on for months because they did not want their babies to change "wet nurses." They could buy any arrangements they wished. A major source of criticism continues to come from women whose education and incomes far exceed those of average men and women. Most are professionals: writers, nurses, and academics. They appear to be successful in their careers, incomes, heterosexual relationships, and child rearing. They have the money, the talent, and the knowledge of resources necessary to adapt to motherhood without loss or constriction of their careers or incomes. They also have the money necessary to create their own environments in labor-delivery suites that provide traditional obstetric care. *A Good Birth, a Safe Birth* is written by two such women.[6] Among their recommendations are:

> Summary: How to have a normal birth and avoid an unnecessary cesarean.
>
> Labor
>
> 6. Hire a monotrice to monitor your labor and your baby's heart rate, especially if that is the only way you can avoid a fetal monitor.
> 9. Have at least one woman you know and like with you—your doula—in addition to your husband.

This provides the patient, who senses control over every aspect of her life, control over the labor and delivery process as well. Lest you think I am making a major issue of an isolated publication, similar attitudes are found in *Immaculate Deception. A New Look at Women and Childbirth in America* by Suzanne Arms.[23] Unfortunately, there is a fair amount of deception in the book. Another is *Silent Knife. Cesarean Prevention and Vaginal Birth After Cesarean* by Nancy Wainer Cohen and Lois J. Estner.[24] Both of these women have experienced vaginal delivery after an initial cesarean birth. Another example is *How to Avoid a Cesarean Section* by Christopher Norwood.[25] I avoid referring to this as "yuppie obstetrics," because identical goals are also found in a totally different group of women. Ina May Gaskin[26] wrote *Spiritual Midwifery*. She was the first lay midwife at "The Farm" in Summertown, Tennessee, a vegetarian agricultural commune whose spiritual orientation is in the Zen tradition. Its original members were largely drop-outs from the drug and hippie life who accepted Zen and emigrated to rural Tennessee to create a successful self-supporting community. They describe themselves as follows: "We are not just a community. We are a church. We hold our land in common, and share fortunes. No money is exchanged for goods or services among the people of our community." Their

obstetric principles are identical, in respect to patient and lay midwife responsibilities, to those of our upper-class critics. On "The Farm," becoming a mother produces no undesirable changes in life-style or social or economic status.

Women who do not compromise their goals because they become mothers represent the major source of our lay critics. We might have speculated that the opposite would be true. The explanation of this apparent contradiction seems clear. Women who have control over their life-styles, particularly control of the impact of children, also wish to have control over childbirth as well. Women who do not have the resources or support to avoid the negative impact of child rearing have the much more serious problem of loss of control of their lives. The importance of the events of 12 hours of labor pales for them when contrasted with the many years of loss of their own growth potential. Recognize that our critics do not wish any change from their mode of living, whether in the farm commune or "yuppieland." These are not radicals in the sense that they wish to change the structure of society—only to dominate their own environments. The radical critics of our specialty have little to say about obstetric practice. Mary Daly[27] was an associate professor of theology at Boston College in 1978 when she published *Gyn/Ecology, the Metaethics of Radical Feminism.* Two successive chapter headings are labeled: Chapter Seven. American Gynecology: Gynocide by the Holy Ghosts of Medicine and Therapy and Conclusion and Afterword to Chapter Seven. Nazi Medicine and American Gynecology: A Torture Cross-Cultural Comparison. Because some of you will not rush to read the book, I will tell you the ending of this section. We came out in a tie with Dr. Mengele. More important, she is sympathetic to feminists who "wish to explore the possibility of parthenogenesis," potentially realistic these days with the availability of unfertilized ova in the laboratory. She would then achieve her "final solution," which in another frame of reference she calls a "mister-ectomy." In spite of this intense hatred of men in general and male gynecologists specifically, I could find only four sentences concerning obstetrics in 424 pages of text. Three complained about the use of scopolamine in the present tense, and the fourth was this inexplicable comment on natural childbirth: "Natural childbirth . . . is nothing more than a romanticized means of helping women to better adjust to the abnormal and intensely painful delivery process mandated by men." No alternative suggestions for practice are offered.

If my hypothesis is correct, if the wish for self-reliance in childbirth is in the main important to women whose life goals will not be altered significantly by a neonate, what about the rest? Most women do not live in communes or have the incomes, education, support systems, and sophistication to avoid the limiting effects children place on their lives. For example, a little more than one fifth of our patients are single, widowed, or divorced at the time they are delivered. Few have a "significant other." I believe that is the current term for father but not husband. In Korte and Scaer's book,[6] the word "husband" is used only with positive connotations such as the importance of the husband's presence during labor. The term "father" is used when the male fails to provide proper support. Of course he fails because the hospital or physician would not allow him to participate, never because he was long gone those many months. No "yuppie" father/husband would do such a thing. I think it is pointless to detail the specific differences between the "yuppie" or "The Farm" women and the bulk of our patients. All of the factors that will cause the vast majority of women to alter their life-styles after childbirth also interfere with their ability to succeed in achieving nonmedicated births consistently. This is no reason to deny them education or preparation for childbirth. It never occurs to Mss. Korte, Scaer, Gaskin, Arms, Cohen, Estner, or Norwood that there is a whole imperfect world out there of women to whom the fates have not been as kind: women who, for a variety of reasons, are not as prepared to meet the responsibilities of pregnancy and delivery. I find no evil in using our professional knowledge and skills to help them through labors they find painful and threatening. This is an issue our highly educated critics, blessed with the life-styles they want, ignore.

In summary, we must be certain that the words we use connote the same meaning to all, that our symbols specify, not obscure. Past and present critics of obstetric practice in the United States in this century are women whose life-styles are not injured by childbearing or rearing. These women who control the particulars of their lives wish to control the circumstances of childbirth as well. When their desires are consistent with our knowledge of medical science we should admire their independence and be supportive; when inconsistent, we should have the courage to reject the criticism without renouncing the critic. If my hypothesis that there is a positive relationship between female equality as so defined and the acceptance of personal responsibility for childbirth is correct, then the bulk of women in our society will expect to receive our help even when no specific obstetric pathology exists. We must not continue to respond to criticism by extending the use of our diagnostic and therapeutic technology beyond its proved usefulness as tested by the scientific method. Finally, we know we do not have either the power or the desire to "seize, stake out, or colonize" childbirth or the ability to remove all the limits society places on

women, but we can protect our own female professionals from the potential career constraints of childbirth and childrearing.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Biochemical and physiologic characterization of follicle regulatory protein: A paracrine regulator of folliculogenesis

Tsutomu Ono, M.D., Joseph D. Campeau, M.S., Eric A. Holmberg, B.A., Robert M. Nakamura, Ph.D., Eryn L. Ujita, B.A., Dawn L. Devereaux, B.A., Sharon A. Tonetta, Ph.D., Robin DeVinna, B.A., Maria Ugalde, M.S., Gere S. diZerega, M.D.

Los Angeles, California, and Yamagata, Japan

Further purification of a porcine follicular fluid fraction, referred to as follicle regulatory protein, that inhibits granulosa cell aromatase was performed and the results of in vitro bioassays with these highly purified reagents are reported. The 0% to 35% saturated ammonium sulfate extract of porcine follicular fluid was percolated through an orange A dye matrex gel column and the bound fraction was eluted. Further purification of 0% to 35% orange A–bound fraction of porcine follicular fluid was performed by anion exchange chromatography with the use of the Mono Q column. Mono Q eluents containing follicle regulatory protein activity were injected onto a Mono P hydrogen ion–exchange column. Samples obtained from Mono P chromatography were injected onto preparative and analytical scale gel exclusion columns. Eluent fractions in the apparent molecular weight of 16,000 daltons were tested for aromatase inhibition. Throughout each step, parallelism of an aromatase inhibitor was apparent in both a cell-free microsomal assay and a granulosa cell assay. Follicle regulatory protein, purified about 6666-fold from the orange A–bound fraction of porcine follicular fluid, had a 50% inhibitory concentration of 25 ng/ml for granulosa cell aromatase activity. (Am J Obstet Gynecol 1986;154:709-16.)

Key words: Follicle regulatory protein, granulosa cell, aromatase

The dynamics of follicle recruitment and growth are not strictly functions of time in that they are controlled, in part, by intraovarian events. We sought to examine how the preovulatory follicle maintains its dominance over other follicles in either ovary as well as how this dominance may participate in the preservation of the ovulatory quota. We found evidence that the graafian follicle produces and secretes a hormone-like protein, referred to as follicle regulatory protein, which affects the responsivity of other follicles to gonadotropin stimulation.

Follicle regulatory protein is secreted by human[1, 2] and porcine[3] granulosa cells and does not inhibit secretion of follicle-stimulating hormone by pituitary cells in vitro.[4, 5] Therefore, follicle regulatory protein has biologic properties different from those of inhibin. Follicle regulatory protein has been shown to: (1) inhibit the increase in ovarian weight and serum estradiol levels in response to human menopausal gonadotropin in hypophysectomized, immature, diethylstilbestrol-treated rats[6, 7]; (2) delay follicular maturation into regularly cycling monkeys as evidenced by decreased serum estradiol levels, prolongation of the follicular phase, and anovulation or luteal phase dysfunction in the presence of normal serum gonadotropin levels[8]; (3) inhibit follicle-stimulating hormone induction of luteinizing hormone–human chorionic gonadotropin receptors in porcine granulosa cells[9]; (4) inhibit follicle-stimulating hormone–responsive adenylate cyclase activity in porcine granulosa cells[10]; and (5) inhibit in vitro microsomal aromatase[11, 12] and 3β-hydroxysteroid dehydrogenase activities,[12] thereby altering production and secretion of progesterone from granulosa cells.[13-16] This follicular regulatory protein is not toxic to granulosa cells in vitro and its effects are reversible.[11, 13]

The studies listed above were performed with a follicle regulatory protein reagent prepared by ammonium sulfate precipitation, followed by dialysis and further fractionation with the use of Matrex gel orange A chromatography. Here, the further purification of follicle regulatory protein and the results of in vitro bioassays performed with these more highly purified reagents are reported; these address the physiologic role of follicle regulatory protein and the process of dominant follicle selection in women.

Material

A fast protein liquid chromatography system consisting of a GP-250 gradient programmer, two P-500 high-precision pumps, a UV-1 single path ultraviolet monitor, a pH monitor, a flow-through pH electrode, a FRAC-100 fraction collector, an REC-482 two-channeled recorder, a V-7 valve injector, a 10 ml Superloop, and a 50 ml Superloop as well as an HR 5/5 Mono bead anion exchange Mono Q column (0.5 by 5 cm), an HR 5/20 Mono bead hydrogen ion exchange Mono P column (0.75 by 30 cm), and molecular weight standards was obtained from Pharmacia, Inc., Piscataway, New Jersey. A Gilson (Middleton, Wisconsin) FC-80K fractionator and an ISCO (Lincoln, Nebraska) Model UA-5 detector were also used.

High-performance liquid chromatography included an M-730 data module, a Model 720 system controller, Model 6000 A and M45 solvent delivery systems, a Model 450 ultraviolet variable wavelength detector, and an automated 710 B sample processor and Diaflo membrane (PM10, molecular weight 10,000 cutoff) purchased from Amicon (Lexington, Massachusetts). The Bio-Sil TSK-250 analytical gel permeation column (0.75 by 60 cm, TSK analytical column) was provided by Bio-Rad (Richmond, California). The Spherogel TSK-G3000SWG preparative column (2.1 by 60 cm), Spherogel TSK-Guard column (2.1 by 7.5 cm), and pH monitoring equipment were obtained from Beckman Instruments, Fullerton, California. All chemicals and reagents were purchased from Sigma Chemical Co., St. Louis, Missouri, and radioisotopes were obtained from New England Nuclear, Boston, Massachusetts. Bufferlyte, pH 4 to 8, was provided by the Pierce Chemical Co., Rockford, Illinois. Dialysis tubing (6000 to 8000 molecular weight exclusion) was obtained from Spectrum Medical Industries, Los Angeles, California. Pooled porcine follicular fluid was provided by Dr. Gabriel Bailey of the Contraceptive Development Branch, National Institute of Child Health and Human Development, and fresh porcine follicular fluid was aspirated from porcine ovaries obtained from a local slaughterhouse. All procedures were done at room temperature unless otherwise stated.

Methods

Ammonium sulfate precipitation of follicular fluid. From a stock of frozen porcine follicular fluid, 1 L was slowly thawed and centrifuged at 4° C in a Sorvall RC-2B at 5000 rpm for 30 minutes to remove particulates. To the supernatant, 320 gm of crystalline ammonium sulfate was slowly added under gentle stirring in an ice bath. This solution was slowly stirred for an additional 2 hours and centrifuged at 5000 rpm for 30 minutes at 4° C. The precipitate was resuspended in 1000 ml of chilled 35% saturated ammonium sulfate solution, stirred for 2 hours in an ice bath and allowed to stand at 4° C overnight. The precipitate (0% to 35% saturated ammonium sulfate) was obtained by centrifugation. The precipitate was dissolved in 0.05 mol/L Tris hydrochloride, pH 7.5, and 0.1 mol/L sodium chloride (buffer A), dialyzed against three changes of distilled water, and centrifuged. The supernatant fraction was stored at −20° C.

Dye matrex orange A chromatography. A 100 ml charge containing approximately 10 gm of the 0% to 35% saturated ammonium sulfate extract of porcine follicular fluid was slowly percolated through an orange A matrex gel column (4 by 25 cm, 300 gm of dye matrex gel orange A) equilibrated with 0.02 mol/L Tris hydrochloride, pH 7.5 (buffer B) at 4° C. After loading, the column flow was halted for 1 hour to allow binding to occur. Unbound material was eluted with approximately 600 ml of buffer B at a flow rate of 1 ml/min and the bound fraction was eluted with 400 ml of 0.5 mol/L potassium chloride in buffer B. Fractions of 5 ml were collected. Fractions containing activity were pooled, dialyzed against distilled water, and lyophilized. This lyophilized fraction is referred to as 0% to 35% orange A–bound material.

Separation of follicle regulatory protein from 0% to 35% orange A–bound material by anion-exchange chromatography. The 0% to 35% orange A–bound material was further purified by anion-exchange chromatography with the Mono Q column by a fast protein liquid chromatography system. Gradient elution was controlled with a GP-250 gradient programmer. All buffers were filtered through 0.22 μm cellulose acetate filters (HAWP 04700) and then degassed prior to fast protein liquid chromatography. For each Mono Q run, 20 mg of 0% to 35% orange A–bound material dissolved in 1 ml of buffer B was applied as a charge to a Mono Q column previously equilibrated with buffer B. After loading, the column was washed with 5 ml of buffer B to elute unbound material at a flow rate of 1 ml/min and the bound material was eluted with the use of a linear gradient of sodium chloride in buffer B (0.0 to 0.4) mol/L during a period of 20 minutes. The column was stripped by means of a 2-minute wash with 1 mol/L sodium chloride in buffer B and then reequilibrated with starting buffer. Eluent fractions that contained biologic activity were pooled and dialyzed against distilled water to remove salt and lyophilized. Mono Q eluents containing follicle regulatory protein activity are referred to as Mono Q follicle regulatory protein.

Separation of follicle regulatory protein from Mono Q follicle regulatory protein by hydrogen ion–exchange chromatography. Twenty milligrams of Mono Q follicle regulatory protein was dissolved in 0.025 mol/L *bis* Tris hydrochloride, pH 7.1 (buffer C) and

injected with the previously described fast protein liquid chromatography system onto a Mono P hydrogen exchange column previously equilibrated with buffer C at a flow rate of 1 ml/min. After the column was washed with buffer C for 10 minutes, the sample was eluted isocratically with 50 ml of Pierce Bufferlyte 4-8 (diluted 1:20 in distilled water and adjusted to pH 4.0). A 1 ml aliquot of buffer C containing 2 mol/L sodium chloride was injected onto the column and elution with buffer C was continued for an additional 10 minutes. The pH values of all fractions (1 ml) was determined on a pH meter. Fractions that contained biologic activity were pooled and dialyzed against distilled water to remove ampholytes and referred to as Mono P follicle regulatory protein.

Separation of follicle regulatory protein from Mono P follicle regulatory protein by gel-permeation chromatography. Preparative scale gel-exclusion chromatography was performed with a Spherogel TSK-G3000SWG column fitted to a Waters high-performance liquid chromatography. Buffer D containing 0.02 mol/L sodium phosphate and 0.1 mol/L sodium chloride, pH 7.0, was used as an eluent. Samples (2 to 8 ml) obtained from Mono P chromatography were reduced to approximately 2 ml by ultrafiltration with the use of an Amicon Diaflo system with PM 10 membranes just before column injection. Eluent fractions in the apparent molecular weight range 10,000 to 20,000 daltons were pooled, dialyzed, and lyophilized. Those fractions with follicle regulatory protein activity are referred to as preparative TSK follicle regulatory protein.

Estimations of molecular weight by size-exclusion chromatography on preparative TSK-G3000SWG and analytical TSK-250 columns were performed with the use of gel filtration standards of blue dextran (molecular weight 2,000,000 daltons), bovine serum albumin (molecular weight 67,000 daltons), ovalbumin (molecular weight 45,000 daltons), and ribonuclease A (molecular weight 13,700 daltons).

All determinations of protein concentrations were performed by the method of protein dye binding. Tests for statistical significance were performed with Duncan's new multirange test.

Bioassays of follicle regulatory protein activity

Granulosa cell assays. Porcine granulosa cells (10^5 per well in serum-free medium 199) were incubated for 3 hours (37° C, 5% carbon dioxide, 90% nitrogen) with or without either 200 to 800 μg of orange A–bound material or serial dilutions of a more purified preparation of follicle regulatory protein (total volume = 0.5 ml). Ham's F-10 medium with Hepes buffer (0.5 ml) was added and tubes were centrifuged at 200 × g for 15 minutes. Supernatants were discarded, and cells were resuspended in Ham's F-10 medium with Hepes buffer (0.5 ml), then divided into two aliquots (100 μl each). Androstenedione (30 ng/ml) was added and tubes were incubated in a shaking water bath for 2 hours at 37° C. Normal saline solution (0.8 ml) was added to all tubes, which were then centrifuged at 1000 × g for 15 minutes. Supernatants were decanted, extracted two times with ether, then dried under nitrogen. Samples were resuspended in gel buffer and conversion of androgen was measured by established radioimmunoassay.

Cell-free microsomal aromatase assay. The cell-free microsomal aromatase assay was performed as described and validated previously.[11] Microsomal fractions were prepared from human placentas obtained immediately after delivery. The fresh human placentas were weighed and homogenized with buffer F (0.5 mol/L potassium phosphate and 0.25 mol/L sucrose, pH 7.0) on a Waring Blendor for 1 minute. The homogenate was centrifuged at 800 × g for 30 minutes and the resulting supernatant was centrifuged at 120,000 × g for 1 hour. The precipitate was resuspended in buffer F containing 50% glycerol and stored in the freezer (−60° C).

Test fractions of 0.02 ml were preincubated with 0.3 ml of placental microsome fraction in a 1:60 dilution of stock for 20 minutes at 37° C. A solution (0.1 ml) containing carbon 14–labeled androstenedione (2×10^{-5} mol/L, 52 μCi/mmol), 0.2 mol/L nicotinamide, and 10^{-4} mol/L reduced nicotinamide adenine dinucleotide phosphate in a 1:10 dilution of buffer F was added to the preincubated mixture and incubated for 30 minutes at 37° C, after which the reaction was terminated by ether extraction, 5 ml two times. All incubations were performed in duplicate. Ether extracts were taken to dryness under nitrogen and resuspended in 2 ml of 2,2,4-trimethylpentane (J. T. Baker, Phillipsburg). These solutions were separated by a Celite column with cylohexane/benzene (97:3) to separate androstenedione and testosterone followed by 15% ethyl acetate/2,2,4-trimethylpentane to separate estrogen. The fractions were evaporated to dryness under nitrogen after which 10 ml of scintillation fluid was added for counting.

Conversion rates from androstenedione to estrogen in each fraction were calculated. Inhibitory activities determined by the cell-free aromatase assay were expressed as the percentage of inhibition of conversion rates in sample fractions divided by those in control fractions.[11]

Results

Ammonium sulfate precipitation of porcine follicular fluid. Previously we reported the recovery of follicle regulatory protein as evidenced by inhibition of aromatase in the hypophysectomized immature female rat bioassay from the dye matrex chromatographic

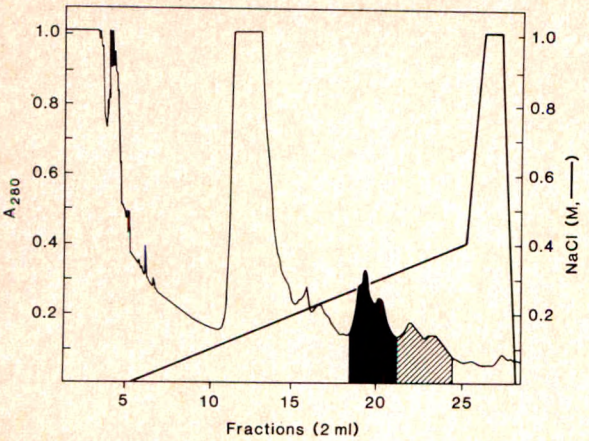

Fig. 1. Ion-exchange elution profile of the dye matrex orange A–bound material developed through a Mono Q column by a sodium chloride gradient under fast protein liquid chromatography conditions. The fractions that contained biologic activity are contained in the *shaded area* (ID_{50} = 120 μg/ml in granulosa cell assay).

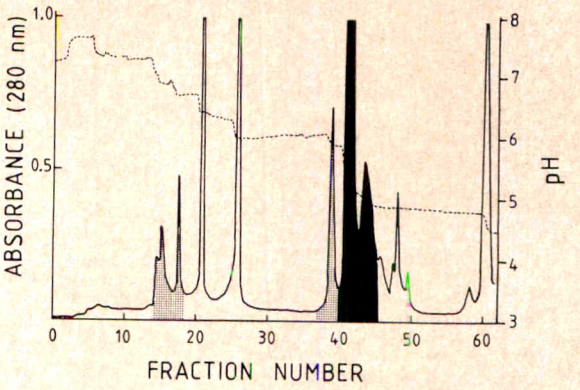

Fig. 2. Hydrogen ion–exchange elution profile of the Mono Q material developed through a Mono P column by a change in pH. The fractions that contained biologic activity are contained in the *shaded areas* (pI = 4.5; ID_{50} = 15 μg/ml in cell-free aromatase assay; ID_{50} = 50 μg/ml in granulosa cell assay).

fraction of the 10% to 55% saturated ammonium sulfate precipitate of porcine follicular fluid.[3] Here we report the relative follicle regulatory protein activities in different fractions of saturated ammonium sulfate–precipitated porcine follicular fluid. After loading of 0% to 35%, 35% to 50%, and 0% to 50% saturated ammonium sulfate onto dye matrex orange A columns, each bound fraction (0% to 35%, 35% to 50%, and 0% to 50% orange A–bound material) was dialyzed and lyophilized. The 50% inhibitory dose (ID_{50}) of each fraction of orange A–bound porcine follicular fluid was determined in the cell*f*ree aromatase assay. The 0% to 50% and 35% to 50% orange A–bound material contained ID_{50}s of approximately 400 μg/ml, whereas 0% to 35% orange A–bound material contained an ID_{50} of 200 μg/ml. Accordingly, the 0% to 35% saturated ammonium sulfate fraction of porcine follicular fluid was used for all further studies reported here.

Separation of follicle regulatory protein from 0% to 35% saturated ammonium sulfate by dye matrex orange A chromatography. The protein fraction that eluted from the matrex gel orange A column before the addition of 0.5 mol/L potassium chloride to elution buffer A (unbound) comes out in two distinct peaks, neither of which exhibited biologic activity in bioassay. One peak absorbing at 280 nm was eluted from the column with 0.5 mol/L potassium chloride, which contained essentially all of the inhibitory activity. The total amount of protein that eluted in this 0.5 mol/L potassium chloride portion was equal to 9% of the 0% to 35% saturated ammonium sulfate fraction of porcine follicular fluid. The ID_{50} of the orange A–bound 0.5 mol/L potassium chloride fraction for the cell-free aromatase assay was 200 μg/ml. The average yield of orange A–bound material was 620 μ/ml. When unbound follicular fluid fractions were recycled through the orange A column, less than 10% of the total activity was recovered, suggesting that the efficiency of the initial pass-through approached 90%.

Separation of follicle regulatory protein from 0% to 35% orange A–bound material by means of ion-exchange chromatography. The Mono Q HR5/5 ion-exchange column developed via fast protein liquid chromatography separated a follicle regulatory protein fraction from 0% to 35% orange A–bound material with an ID_{50} of 30 μg/ml in the cell-free aromatase (Fig. 1) and 120 μg/ml in the granulosa cell assay. With the use of a 0 to 0.4 mol/L sodium chloride gradient, follicle regulatory protein was recovered in a range of 0.28 to 0.32 mol/L with a yield of 10% from 0% to 35% orange A–bound material.

Separation of follicle regulatory protein from mono Q follicle regulatory protein with use of hydrogen ion–exchange chromatography. A typical hydrogen ion–exchange chromatogram of Mono Q follicle regulatory protein eluted through a Mono P column via fast protein liquid chromatography with biologic activity recovered at pH 6.5 and 4.5 *(shaded areas)* is depicted in Fig. 2. From a 16 mg load, biologic activity could be recovered in a relative concentration of 0.02 μg/ml (pH 6.5) and 0.04 μg/ml (pH 4.5). The overall yield was 130 μg (pH 6.5) and 1.1 mg (pH 4.5) from a 16 mg charge of Mono Q follicle regulatory protein. The pH 4.5 follicle regulatory protein has an approximate ID_{50} of 15 μg/ml in the microsomal aromatase assays and an ID_{50} of 50 μg/ml in granulosa cell assay.

Separation of follicle regulatory protein from mono P follicle regulatory protein (pH 5.5) with use of gel-permeation high-performance liquid chromatography. Fig. 3 represents the elution profile from a prep-

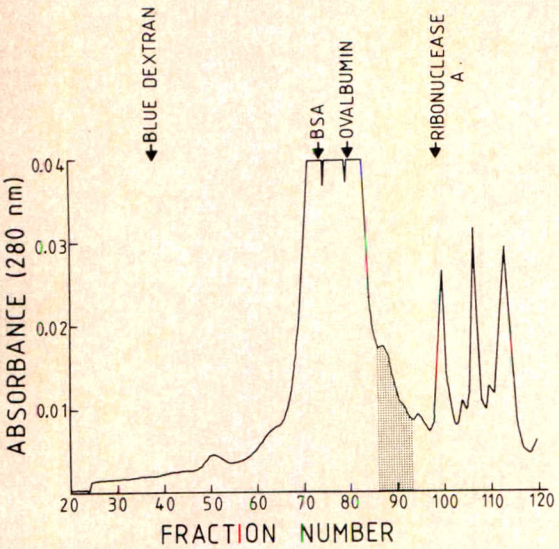

Fig. 3. Elution profile of Mono P, pH 4.5 follicle regulatory protein of porcine follicular fluid recovered from Spherogel preparative TSK-G3000SWG gel permeation column. The *shaded area* corresponds to a molecular weight of 12,000 to 20,000 daltons. A total of 2 ml of pH 4.5 Mono P follicle regulatory protein (2 to 5 mg of protein) was injected per elution at a flow rate of 2.0 ml/min, 300 psi, for 120 minutes. The fraction that contained biologic activity is contained in the *shaded areas* (cell-free aromatase assay: ID_{50} = 1.2 μg/ml; porcine granulosa cell aromatase: ID_{50} = 0.8 μg/ml).

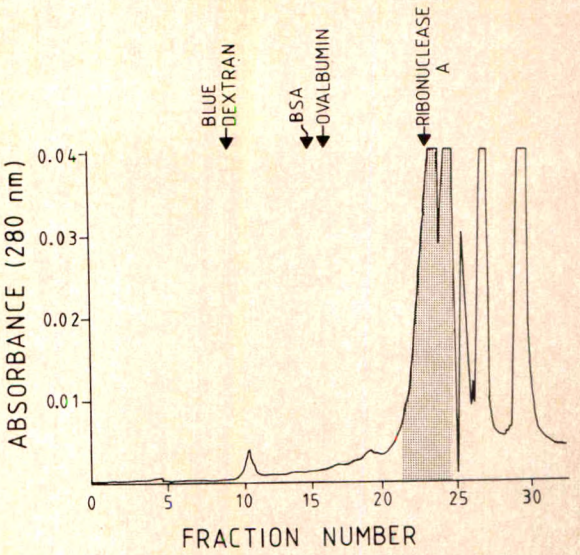

Fig. 4. Chromatography of preparative TSK follicle regulatory protein on analytical TSK-250SW column. A total of 200 μl of preparative TSK follicle regulatory protein was injected per elution. The initial peak (46.03 to 47 minutes) contained aromatase inhibitory activity in the placental cell-free (ID_{50} = 0.030 μg/ml) and porcine granulosa cell (ID_{50} = 0.035 μg/ml) assays.

arative TSK-3000 SW column of Mono P, pH 4.5 follicle regulatory protein. The fraction containing inhibitory activities corresponds to a molecular weight range of 10,000 to 20,000 daltons. The microsomal aromatase inhibitory activity is recovered in 10% of the protein load with an ID_{50} of 5 μg/ml.

The fraction containing follicle regulatory protein on preparative TSK-3000 SW columns was eluted through the analytical TSK-250 column (Fig. 4). The follicle regulatory protein activity was present in fractions corresponding to a molecular weight of 16,000 daltons. The ID_{50} of follicle regulatory protein after analytical TSK-250SW separation was 25 ng/ml for the cell-free aromatase assay and 30 ng/ml for the granulosa cell assay.

Throughout each step, parallelism of follicle regulatory protein was apparent in both the cell-free microsomal (Fig. 5) and granulosa cell (Fig. 6) assays. Follicle regulatory protein was purified about 6666-fold from the orange A–bound fraction of porcine follicular fluid (Table I).

Comment

These data report the relative utilities of biochemical techniques in the purification and assay of follicle regulatory protein wth aromatase inhibition used as the hallmark of activity. Reported here are the requisite steps for purifying follicle regulatory protein from follicular fluid and the relative increases in specific activities and yields from each step. Ledwitz-Rigby et al.[15] confirmed the observations of Kling et al.[3] that follicle regulatory protein inhibits aromatase activity in porcine granulosa cells from medium-sized follicles. Although these observations can be extended to the small follicles of granulosa cells, an effect of follicle regulatory protein on estrogen secretion by cells from large follicles was undetectable. Since reduced aromatase activity in atretic antral follicles is due to a loss of existing aromatase activity rather than a failure to acquire this activity initially, a decrease in aromatase activity is probably an early event in the atretic degeneration of antral follicles. Thus, in follicular atresia, it is the lack of aromatase and not androgen substrate per se that limits estrogen production. The demonstration that follicle regulatory protein acts only on granulosa cells of less mature antral follicles to inhibit aromatase suggests a role for follicle regulatory protein in atresia.

In addition to inhibiting aromatase activity, follicle regulatory protein induces a biphasic effect on progesterone secretion by granulosa cells from sows[16] and rats.[13] At low doses, follicle regulatory protein stimulates progesterone secretion while at higher doses it is inhibitory. When follicle regulatory protein was added to human menopausal gonadotropin-treated granulosa cells, there was a follicle regulatory protein–associated, dose-dependent decrease in progesterone concentrations in culture media and cytosol as well as microsomal

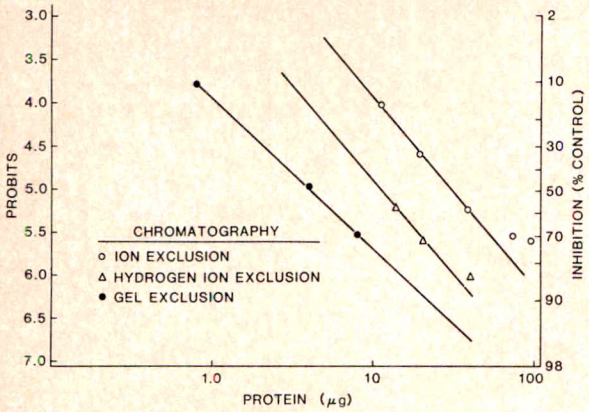

Fig. 5. Inhibition of cell-free placental aromatase activity by each purification step of follicle regulatory protein.

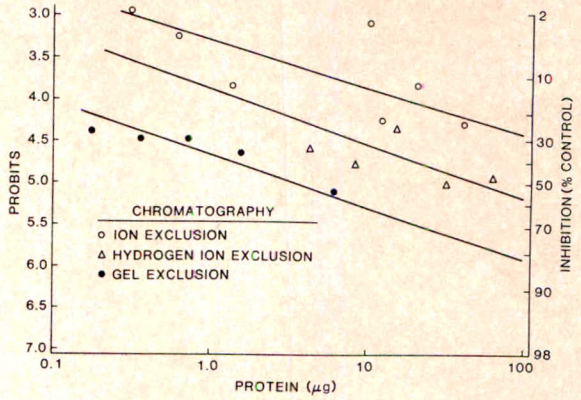

Fig. 6. Inhibition of granulosa cell aromatase activity by each purification step of follicle regulatory protein.

3β-hydroxysteroid dehydrogenase activity. These observations are similar to those of Ledwitz-Rigby et al.,[15] who found that follicle regulatory protein stimulated basal progesterone secretion by porcine granulosa cells with small and medium follicles but not with large follicles. Schreiber and diZerega[13] examined the interactions of follicle regulatory protein and ovine follicle-stimulating hormone on 20α-dihydroprogesterone production in rat granulosa cell cultures. With low doses of ovine follicle-stimulating hormone (6.25 to 37.5 ng/ml), follicle regulatory protein inhibited ovine follicle-stimulating hormone stimulation of 20 α-dihydroprogesterone production. This inhibition by follicle regulatory protein was overcome when ovine follicle-stimulating hormone was increased to 50 ng/ml.

Testosterone appears to sensitize granulosa cells to the action of follicle regulatory protein on steroid secretion.[20] Atretic follicles have been reported to contain higher androgen levels than nonatretic follicles. While androgens have long been thought to contribute to atresia, the exact cause-and-effect relationship between androgens and atresia has remained elusive. Elevated intrafollicular androgen levels may enhance the sensitivity of specific follicles to follicle regulatory protein, causing inhibition of steroidogenesis (especially estrogen production) necessary for follicular growth.

It is unlikely that the effect of follicle regulatory protein on granulosa cell steroidogenesis is due to toxicity of the follicular fluid preparation, since follicle-stimulating hormone is able to overcome follicle regulatory protein inhibition of whole granulosa cell progesterone secretion as well as microsomal 3β-hydroxysteroid dehydrogenase activity, and the effects of follicle regulatory protein on whole porcine,[16] and rat[13] granulosa cell aromatase activity are reversible. Although follicle regulatory protein inhibits aromatization in vitro, it is unlikely that the action of follicle regulatory protein on progesterone secretion simply reflects local reduction in estrogen production, since physiologic concentrations of estradiol suppress progesterone production in human granulosa cells, probably by suppressing 3β-hydroxysteroid dehydrogenase activity. Follicle regulatory protein may have more than one site of action in the cell, or it may contain more than one active element.

Since follicle regulatory protein is an effective inhibitor of aromatase activity, the possibility remains that the buildup of endogenous intracellular androgen by the follicle regulatory protein–mediated inhibition of aromatase may alter 3β-hydroxysteroid dehydrogenase activity. Aromatizable androgens inhibit follicle-stimulating hormone–stimulated progesterone synthesis in porcine granulosa cells at a step distal to cyclic adenosine monophosphate formation. Further, aromatizable androgens markedly increase pregnenolone accumulation in follicle-stimulating hormone–treated cultures. Previous studies also demonstrated that follicle regulatory protein has no apparent effect on follicle-stimulating hormone receptor binding in granulosa cells.[3, 8] Therefore, the stimulatory effect of follicle regulatory protein is probably not a direct function of the follicle-stimulating hormone receptor. Recent studies carried out on follicle-stimulating hormone–augmented adenylate cyclase activity indicate that follicle regulatory protein inhibits follicle-stimulating hormone induction of adenylate cyclase.[9] Interestingly, reports describing the effects of follicle regulatory protein on human placental microsome preparations suggest that follicle regulatory protein noncompetitively inhibits aromatase[10] and 3β-hydroxysteroid dehydrogenase activities.[12]

Steroidogenic enzymes in granulosa cells appear to have follicle-stimulating hormone–dependent differential sensitivities to follicle regulatory protein in vitro. Follicle regulatory protein in concentrations of 50 to 200 μg/ml inhibits aromatase activity in granulosa

Table I. Purification of a follicular regulatory protein from porcine follicular fluid with the use of cell-free placental aromatase and granulosa cell assays

Stage of purification	*Protein added (mg)*	*Protein recovery (%)*	*Active mass (mg)*	*Yield (mg/100 ml)*	*Activity*		*Purification (fold)*

cells[13, 16] while stimulating 3β-hydroxysteroid dehydrogenase activity. When the concentration of orange A–bound follicle regulatory protein is further increased to 500 μg/ml, both aromatase and 3β-hydroxysteroid dehydrogenase activities are inhibited. Granulosa cells exposed to follicle-stimulating hormone alone produce more estrogen and less progesterone. However, when granulosa cells are exposed to follicle-stimulating hormone in the presence of follicle regulatory protein, more progesterone and less estrogen are produced. These observations suggest that follicle regulatory protein alters the dose-response relationship between follicle-stimulating hormone and 3β-hydroxysteroid dehydrogenase activity in granulosa cells. Thus follicle regulatory protein may play a role in modulating the relative secretion of progesterone and estrogen by granulosa cells in response to follicle-stimulating hormone stimulation.

Kinetic analysis of follicle regulatory protein inhibition of aromatase and 3β-hydroxysteroid dehydrogenase activities is suggestive of noncompetitive inhibition.[10, 12] The inhibitory effects of follicle regulatory protein on aromatase and 3β-hydroxysteroid dehydrogenase activities in placental microsomes were associated with a decrease in the apparent maximum velocity without a detectable change in the apparent Michaelis constant of the enzyme. Thus the possibility that follicle regulatory protein treatment decreases enzyme activity by decreasing the affinity of the enzyme for its substrate is unlikely. The apparent inhibition constant for follicle regulatory protein–mediated inhibition of 3β-hydroxysteroid dehydrogenase was 10^{-9} mol/L, at least an order of magnitude more sensitive than the inhibition constant for aromatase inhibition, 10^{-7} mol/L. This derived inhibition constant for follicle regulatory protein is within the biologic concentration of follicle regulatory protein in follicular fluid, assuming that the molecular weight of follicle regulatory protein is 16,000. Schreiber and diZerega[13] and Battin and diZerega,[16] using porcine and rat granulosa cells, also found that 3β-hydroxysteroid dehydrogenase activity was more sensitive than aromatase activity to follicle regulatory protein inhibition.

Most of the effects of follicle regulatory protein on granulosa cell activities may reflect an interplay between the systemic endocrine and local paracrine systems. Since follicle regulatory protein alters ovarian steroidogenesis, it may also have an influence on maintenance of the dominant ovarian follicle. Many investigators have hypothesized that a timely induction or activation of the granulosa cell aromatase system and the concomitant changes in the intrafollicular sex steroid profiles are major determinants of the dominant follicle during its selection early in the ovarian cycle. Once a chosen follicle is producing a significant amount of estrogen, it would then have the capacity to produce more estrogen than neighboring follicles and the selection of the dominant follicle would be assured. In contrast, follicles destined to undergo atresia are not able to produce sufficient estrogen. Thus the developing granulosa cell, through production of paracrine regulatory substances such as follicle regulatory protein, is capable of autoregulating the steroid production of its own and other follicles and thus the subsequent course of folliculogenesis.

A Standard

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

A Standard in Progesterone Therapy

Please see adjacent page for brief summary of prescribing information.

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

(featuring t
Apple Macintosh™ comput

SATURDAY, AUGUST 9, 1986

7:00-7:30 AM
Registration/Breakfast

8:00-10:00 AM

I. Introduction
- A. course goals and objectives
- B. orientation to the equipment *("hands-on")*
- C. overview of course content

II. Word Processing: "Hands-on experience with some practical applications"
- A. introduction to word processing
- B. using MacWrite™ *("hands-on")*
  1. the absolute basics
  2. practical examples
     - a. general: referral letters, manuscripts, personal letters
     - b. special: slide production, newsletters, posters, flyers
  3. adding the "bells and whistles"
     - a. checking your spelling
     - b. customized "form letters"
- C. other word processing programs
  1. Microsoft Word™
  2. specialized programs: ThinkTank™, Page Maker™, etc.
  3. IBM PC word processors: comparisons and compatibility

10:15 AM-12:30 PM

III. Educational Programs:
for your patients, staff, family and you
- A. an animated example of computerized medical education *("hands-on")*
- B. family education: pre-school, school age, college prep, etc.
- C. video disk systems for personal and medical education
- D. patient education: VD, prenatal, contraception, pre-op
- E. on line education: dial-up data bases via telephone lines

SUNDAY, AUGUST 10, 1986

7:00-7:30 AM
Registration / Breakfast

7:30-9:15 AM

IV. Data Base Management:
computerized filing systems
- A. introduction to data base
- B. using Microsoft File™ *("hands-on")*
  1. how to use a data base
  2. how to set up your own data base
  3. additional examples: OB-log book, case lists, practice profile
- C. "heavy-duty" data base applications
  1. relational data bases: Helix™, Omnis 3™, and Interlace™
  2. data import/export: mainframe computers, IBM micro's, word processing programs, other programs

9:30 - 11:15 AM

V. Electronic Spreadsheets:
computerized calculations and projections
- A. definitions and basic concepts
- B. impact of spreadsheets on medical practice
  1. insurance companies, politicians, and medical organizations
  2. diversity of applications: USG, statistics, financial, medical
- C. Using Microsoft Excel™ *("hands-on")*
  1. getting oriented to the spreadsheet
  2. practical examples: EFW by USG, tax calculations, etc.
  3. adding the finishing touches
     - a. fancy formatting
     - b. graphs and charts
- D. Sophisticated examples of spreadsheet applications *("hands-on")*

11:30 – 12:30 PM

VI. Conclusions
- A. Getting your first computer system
  1. how to select and purchase the equipment
  2. software (programs): What do you really need?
- B. What can you, should you, and will you do with your computer?
- C. Microcomputers vs. big computers: the right tool for the right job
- D. The future of medical microcomputing

the facts are known in pelvic inflammatory disease

fact: frequently polymicrobial

Pelvic inflammatory disease is frequently polymicrobial; gonococci, *Escherichia coli*, and *Bacteroides* species are frequently involved.

fact: CDC recommends broad coverage

In treating P. I.D., CDC urges the selection of regimens that are active against the broadest range of possible pathogens.

fact: can bring about infertility

Inadequate treatment can lead to tubal stricture—the major cause of involuntary infertility and an important cause of ectopic pregnancy.

MEFOXIN® (Cefoxitin Sodium, MSD) is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Unruptured ampullary ectopic pregnancy.

and in the treatment of P.I.D.†

the facts still favor Mefoxin® IV/IM

PROVEN* FOR 7 SEVEN YEARS

(Cefoxitin Sodium | MSD)

fact: consistent spectrum of activity**

MEFOXIN has maintained a high level of activity against common pathogens in P.I.D. during 7 years of extensive clinical use.

fact: documented clinical efficacy

CDC has recommended that MEFOXIN, in combination with doxycycline, be one of the regimens for the treatment of P.I.D.

fact: safety comparable to cephalothin

MEFOXIN is generally well tolerated. MEFOXIN does not contain the MTT side chain which has been associated with hypoprothrombinemia and, in some cases, clinical bleeding.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

†MEFOXIN is indicated for the treatment of pelvic inflammatory disease caused by *Escherichia coli*, *Neisseria gonorrhoeae* (penicillinase- and non-penicillinase-producing), *Bacteroides* species including the *Bacteroides fragilis* group, *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and Group B streptococci. MEFOXIN is not indicated for treatment of pelvic inflammatory disease where *Chlamydia trachomatis* is present or suspected.

*proven for treatment of, and prophylaxis against, infections due to indicated organisms

***In vitro* activity does not necessarily imply *in vivo* effectiveness.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see following page.

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

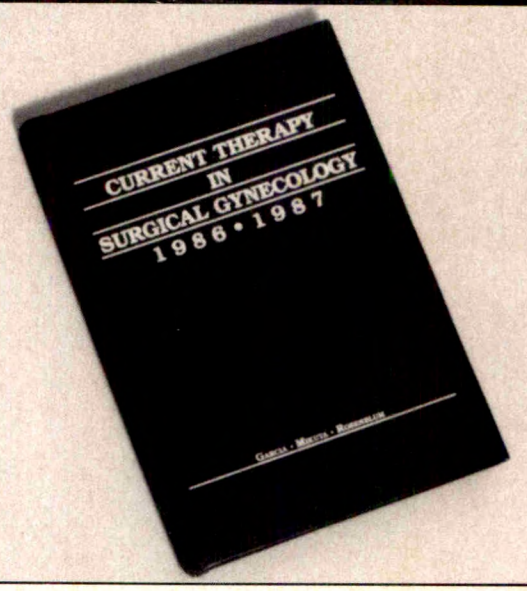
Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk; Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.



How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

CURRENT THERAPY IN SURGICAL GYNECOLOGY 1986-1987

By Celso-Ramon Garcia, M.D.; John J. Mikuta, M.D; and Norman G. Rosenblum, Ph.D., M.D. You no longer have to wade through volumes, chapters and pages of pathophysiology to find just the right treatment for your patients. This heavily illustrated volume targets everything from choice of suture material and instruments to adjuvant therapy, pre- and post-operative care, and non-neoplastic and neoplastic diseases. You make the diagnosis and then check with the experts on the most currently preferred treatment methods. Order your copy today and consult the best! April, 1986. Approx. 256 pages, illustrated. (D-1745-6) Mosby distributes this B.C. Decker, Inc. publication. About $46.00

Save time, call FREE 1-800-345-8500, ext. 15. Our hotline is open 24 hours a day, 7 days a week.

Further studies on genital mycoplasms in intra-amniotic infection: Blood cultures and serologic response

Ronald S. Gibbs, M.D., Gail H. Cassell, Ph.D., Jerry K. Davis, D.V.M., Ph.D., and P. J. St. Clair, B.A.

San Antonio, Texas, and Birmingham, Alabama

Mycoplasma hominis is recovered significantly more often in amniotic fluid of women with intra-amniotic infection than in matched control women, but *Ureaplasma urealyticum* is found in 50% of amniotic fluid samples of both groups. To gain further understanding, we performed blood cultures for genital mycoplasmas and measured serologic responses by a micro enzyme-linked immunosorbent assay method in women with intra-amniotic infection and in control subjects. In blood cultures of 81 women with intra-amniotic infection, *M. hominis* was isolated in two (2.5%) and *U. urealyticum* in 11 (13.6%). In 44 control blood cultures, *M. hominis* was not isolated, and *U. urealyticum* was recovered in eight (18.2%). These differences were not significant. Serologic response was determined in 86 patients. Rise in antibody to *M. hominis* was significantly more common in women with intra-amniotic infection and *M. hominis* in the amniotic fluid than in either women with intra-amniotic infection or control patients without *M. hominis*. For *U. urealyticum* antibody response was significantly more common in the intra-amniotic infection group than in control subjects, but there was no association between antibody response and isolation of this organism in amniotic fluid. When *M. hominis* was found in amniotic fluid or maternal blood, patients were nearly always symptomatic. The high likelihood of serologic response in these cases supports a pathogenic role of *M. hominis* in intra-amniotic infection. The role of *U. urealyticum* remains unclear. (Am J Obstet Gynecol 1986;154:717-26.)

Key words: Blood cultures, enzyme-linked immunosorbent assay, genital mycoplasmas, intra-amniotic infection, serologic responses

Genital mycoplasmas are found with great frequency in the vagina and have been implicated in the pathogenesis of low birth weight infants, postpartum fever, and histologic chorioamnionitis.[1a, 1b] In 1983, we reported on the relationship of clinically evident intra-amniotic infection and genital mycoplasmas in amniotic fluid cultures.[2] *Mycoplasma hominis* was found significantly more often in the amniotic fluid of patients with intra-amniotic infection than in amniotic fluid of matched, asymptomatic control subjects (36% versus 8%, $p < 0.001$). However, in amniotic fluid of cases of intra-amniotic infection, *M. hominis* was usually (83% of cases) found with $>10^2$ colony-forming units per milliliter of high-virulence bacteria. It has thus been unresolved whether *M. hominis* plays a causal role in intra-amniotic infection. *Ureaplasma urealyticum* was present in 50% of amniotic fluid samples from both women with intra-amniotic infection and asymptomatic control women. Thus, on the basis of qualitative cultures, *U. urealyticum* was not associated with intra-amniotic infection.

To gain a further understanding of the role of genital mycoplasmas in intra-amniotic infection, we performed blood cultures for these microbes and also measured serologic responses in patients with intra-amniotic infection and in asymptomatic control women.

Methods

Specimens for this study were collected from patients delivered between January, 1982, and April, 1985, at Medical Center Hospital, San Antonio, Texas. They were mutually exclusive of patients reported previously.[2] The population consisted predominantly of indigent women of Mexican-American extraction. As in previous studies, intra-amniotic infection was defined on the basis of an oral temperature of >100° F (37.8° C) plus two or more of the following: maternal tachycardia (>100 bpm) and fetal tachycardia (>160 bpm), uterine tenderness, foul odor, or leukocytosis (>15,000/mm^3). Patients were considered asymptomatic if they had no temperature >99.8° F (37.8° C) and

no other signs of infection at any time in labor or the puerperium. Women who developed clinically evident endometritis, transient low-grade fever, or other infections were excluded. None of the asymptomatic patients received either prophylactic or therapeutic antibiotics.

Culture technique. From each of these patients, an amniotic fluid sample was collected through an intrauterine pressure catheter that had been inserted for standard obstetric indications. In women with intraamniotic infection, the collection of amniotic fluid preceded antibiotic therapy. Samples were collected from control women who had ruptured membranes >10 to 12 hours. The first 7 ml of amniotic fluid was discarded, and the sample was then transported in a capped syringe and cultured within 60 minutes for aerobes, anaerobes, *M. hominis*, and *U. urealyticum*. For most of the study, cultures of genital mycoplasmas from amniotic fluid were performed by use of a modification of the technique described by Kenny.[3] A tube of urea broth was inoculated with 0.2 ml of amniotic fluid, incubated at 37° C, and observed daily for a color change indicating an increase in pH. Immediately on detection of such a color change, a 0.1 ml aliquot of the broth was transferred onto MES [2-(N-morpholino) ethane sulfonic acid] agar (Sigma Chemical Co, St. Louis, Missouri) and into new broth. The MES agar was then placed in an atmosphere of 5% carbon dioxide:95% nitrogen and incubated, and the new urea broth was incubated aerobically at 37° C. When a color change occurred in the new broth, the MES agar was observed for the presence of genital mycoplasmas. Stains and colony morphologic features were used for identification. Colonies of *U. urealyticum* turn brown with urea test reagent, and colonies of *M. hominis* stain blue with Dienes stain (Difco Laboratories, Detroit, Michigan).

For the last third of the study, amniotic fluid was inoculated onto a Shepard A7B agar plate and broth media, and these were incubated at 37° C. The agar plates were examined 3 days later. Identification of colonies of genital mycoplasmas was made by colonial morphologic features as above. The broth media were incubated as backup in case the primary agar plate did not recover the organism. Isolation rates with the use of these media were comparable to the rates with the technique of Kenny.

The amniotic fluid was also cultured quantitatively for bacteria on a variety of aerobic and anaerobic media.[4]

For culturing of maternal blood, 1 ml was collected aseptically into 9 ml of combination broth and incubated at 37° C for up to 8 days or until a color change indicating a rise in pH occurred.[5] As soon as a color change from orange-red to deep red occurred, the broth was subcultured onto urea agar, arginine agar, and a new combination broth and incubated for 48 hours anaerobically at 37° C. The agar plates were inspected with a stereoscopic microscope at 48 hours. Genital mycoplasmas were identified by colonial morphologic features, as described above. If no color change occurred in the original combination broth, then a blind subculture was taken at 48 hours and processed as above. The maternal blood was also cultured for aerobes and anaerobes, with the use of 5 ml of blood in 70 ml of tryptic soy broth, with 0.05% sodium polyanetholsulfonate. Standard isolation and identification techniques were used.

Samples of infants' blood were collected, when clinically indicated, and cultured for bacteria by standard techniques. As recommended by Galando and McCormack,[5] a blind subculture was taken on the seventh day and processed for genital mycoplasmas.

Serologic techniques. Peripheral maternal blood was collected within 2 days of delivery and again approximately 4 to 6 weeks post partum. Sera were stored at −70° C until assayed. IgG antibodies were detected by a micro enzyme-linked immunosorbent assay. Samples were assayed in blinded fashion by a modification of techniques previously reported.[6, 7] Antigen preparations of each microorganism in logarithmic growth (12 to 20 hours, 10^5 to 10^8 cfu/ml, dependent on mycoplasma strain) were diluted in broth (1:5 to 1:20) and harvested by centrifugation at 10,000 × g for 30 minutes at 4° C after a color change (12 to 20 hours). The pellet was resuspended and washed three times with sterile phosphate-buffered saline, pH 7.3. Bacterial contamination was monitored by inoculation of tryptic soy and blood agar plates. The washed pellet of cells was resuspended in phosphate-buffered saline (5 mg of protein per milliliter) and lysed by addition of 0.05 mol/L carbonate-bicarbonate buffer, pH 10.0, at 37° C. The protein content of each lysate was determined, and all antigens were stored at −70° C.

Antigen lysates for *M. hominis* were diluted in 0.1 mol/L sodium carbonate buffer (pH 9.6) to a concentration of 50 μg/ml; 100 μl of antigen was added to each well (Linbro 96 well microliter E.I.A. plates; Flow Laboratories) and plates were incubated at 37° C for 2 hours. These plates were washed with phosphate-buffered saline (pH 7.3) and blocked overnight with 2% bovine serum albumin in phosphate-buffered saline with 10% horse serum. After removal of the blocking agent, 100 μl of a 1:200 serum dilution was added to each well in duplicate and incubated for 2 hours at 37° C. A background control in which the serum diluent (blocking agent) was substituted for serum was used in addition to positive and negative reference standards. After incubation with serum, the plates were washed

*Data expressed as mean ± SD.

six times, and 100 μl of anti-immunoglobulin conjugate (antiserum to human γ-chain, Kirkegaard and Perry Laboratories) was added. Plates were incubated for 3 hours at 37° C and washed six times with phosphate-buffered saline. Finally, 100 μl of alkaline phosphatase substrate (Sigma Chemical Co.) in 0.05 mol/L sodium carbonate buffer with 0.001 mol/L magnesium chloride (pH 9.8) was added to each well and plates were incubated at 37° C for 45 minutes. The absorbance was determined at 400 nm.

Antigen preparation for the *U. urealyticum* enzyme-linked immunosorbent assay was as described for the *M. hominis* assay. However, some of the other steps differed slightly. The plates were coated with 100 μl of a 50 μg/ml preparation and were stored overnight at 4° C. The plates were then washed with phosphate-buffered saline (pH 7.3) six times and blocked for 2 hours at 37° C with 2% bovine serum albumin in phosphate-buffered saline with 10% fetal calf serum. After removal of the blocking agent, patient sera were diluted 1:200 and 100 μl of this dilution was added to each well in duplicate. Incubation was 2 hours at 37° C. Plates were then washed with phosphate-buffered saline six times and the conjugate was allowed to incubate overnight (18 hours) at 4° C. Plates were washed and alkaline phosphatase substrate (Sigma Chemical Co.) was added to each well. After a 30-minute incubation, plates were read at 400 nm.

Optimal incubation periods and concentrations of antigen, conjugate, and serum were determined by checkerboard titration for all assays. A sample was considered "positive" if its value of absorbance at 400 nm (A_{400}) was greater than the mean normal serum standard value (from nonpregnant adults in Birmingham) +2 SD. A sample was "weakly reactive" if it was twice the mean normal serum standard value but <2 SD above the mean. Seroconversion was defined as change from negative to positive, or negative to weakly reactive, or weakly reactive to positive.

Serologic response was measured in three ways: (1) by comparing number (percent) with seroconversion, (2) by comparing number (percent) with increases in $A_{400} > 0.200$ optical density units, and (3) by comparing mean difference in A_{400} between convalescent and acute sera.

Statistical analysis was by χ^2 or Fisher's exact test (where appropriate) for discrete data and analysis of variance for continuous data.

Results

Blood cultures for genital mycoplasmas and bacteria were collected during labor from 81 patients who had intra-amniotic infection and from 75 patients who were asymptomatic. Of the latter, six subsequently developed endometritis and 25 developed transient puerperal fever; these 31 patients were excluded. The other 44 remained asymptomatic. Characteristics of the intra-amniotic infection and asymptomatic groups are shown in Table I. The groups were similar in mean age, parity, and gestational age. Although both groups had long intervals from rupture of the membranes to delivery, this interval was significantly longer in the intra-amniotic infection group.

Blood and amniotic fluid culture results are shown in Table II. Maternal blood cultures revealed *M. hominis* in two of 81 (2.5%) of all patients with intra-amniotic infection and in two of 33 (6.1%) patients with both intra-amniotic infection and amniotic fluid positive for *M. hominis*. *U. urealyticum* was found more commonly in the bloodstream of both intra-amniotic infection and control groups, but there was no significant difference in ureaplasmemia rates. When genital mycoplasmas were found in the blood, the corresponding isolate was found in amniotic fluid in 18 (86%) of 21 cases. Mycoplasmemia was not detected in any of 60 neonatal blood cultures from infants born to women with intra-amniotic infection. Blood cultures were not collected in asymptomatic infants of control women.

Bacteremia was identified in four (5%) women with intra-amniotic infection, no (0%) asymptomatic women, and six (7.8%) of 77 neonates born after intra-amniotic infection.

Paired sera were available from 52 patients with intra-amniotic infection and from 34 control subjects. (In two women with intra-amniotic infection and one control women, amniotic fluid cultures for mycoplasmas were contaminated.) Characteristics of women in this part of the study are shown in Table III. There were no significant differences in age, parity, gestational age, or interval from amniotic fluid collection to delivery, but the intra-amniotic infection group had a significantly longer mean labor and longer mean interval from rupture of the membranes to delivery. Within the intra-amniotic infection group, there were no significant differences in characteristics between patients with positive and negative amniotic fluid cultures for *M. hominis* or for *U. urealyticum.* Similarly, there were no significant differences in characteristics within the subgroups of asymptomatic patients. Thirty-five women participated in both the blood culture and serologic studies.

The mean (± SD) interval between collection of acute and convalescent sera was 5.4 ± 1.8 weeks, and there were no significant differences in collection intervals among the subgroups shown in Tables IVA and IVB. In the 20 patients with intra-amniotic infection and with *M. hominis* in amniotic fluid, seroconversion occurred in 14 of 20 (70%), and a rise >0.2 optical density units occurred in six (30%). Seventeen (85%) of these patients showed either seroconversion or a rise >0.2 optical density units. Compared with either intra-amniotic infection or control patients without *M. hominis* in amniotic fluid, these serologic changes were significantly greater. Serologic response did not correlate with route of delivery. Of the 14 patients with intra-amniotic infection, *M. hominis* in the amniotic fluid, and seroconversion, six (43%) were delivered by cesarean section. Overall, the cesarean section rate in the intra-amniotic infection group was 46.2% (24 of 52). All IgG values against *U. urealyticum* were positive, but rises >0.2 optical density units in IgG antibodies against *U. urealyticum* occurred significantly more often in the intra-amniotic infection group than in control subjects ($p = 0.007$). However, within the intra-amniotic infection group, there was no association between these rises and isolation of *U. urealyticum* in amniotic fluid. Analysis of serologic changes by mean difference between convalescent and acute levels also led to significant differences.

Four patients whose blood contained *U. urealyticum* had serologic studies performed. Of the two with intra-amniotic infection, one had an IgG rise of >0.2 optical density units. This proportion was similar to that of all patients with intra-amniotic infection. Two patients with ureaplasmemia were asymptomatic, and neither had a rise >0.2. Two patients whose blood contained *M. hominis* had serologic studies. Both had intra-amniotic infection, and both showed IgG rises >0.2.

Comment

M. hominis and *U. urealyticum* are found in approximately 35% to 50% and 50% to 70% of vaginal cultures, respectively.[1] Previous investigators have implicated these microbes in low birth weight infants, postpartum fever, and histologic chorioamnionitis. We have been interested in the role of these organisms in clinically

evident intra-amniotic infection and found *M. hominis* significantly more often in the amniotic fluid of 52 women with intra-amniotic infection than in fluid of 52 matched, asymptomatic control subjects (36% versus 8%, $p < 0.001$).[2] *U. urealyticum* was found in 50% of amniotic fluid cultures in both the intra-amniotic infection and control groups (NS). The amniotic fluid culture results in this series are very similar.

However, these data do not provide conclusive evidence of either a pathogenic role for *M. hominis* or the lack of a pathogenic role for *U. urealyticum* in intra-amniotic infection. Indeed, when *M. hominis* was found in amniotic fluid of intra-amniotic infection patients, it was usually present (15 of 18 cases, 83%) with $>10^2$ cfu/ml of high-virulence bacteria.[2] Accordingly, it is possible that *M. hominis* simply becomes more prevalent in amniotic fluid as a consequence of intra-amniotic infection rather than as its cause. For *U. urealyticum*, it might be that in intra-amniotic infection this organism is present in amniotic fluid in large numbers, whereas in asymptomatic patients it is present in small numbers. Because quantitative cultures of amniotic fluid for genital mycoplasmas were not done, we cannot resolve this point.

To understand further the role of genital mycoplasmas in intra-amniotic infection, we looked for mycoplasmemia and for serologic responses in patients with intra-amniotic infection and in asymptomatic control women.

Presence of an organism in the bloodstream is often accepted as strong evidence of its pathogenicity. However, microorganisms introduced during collection or laboratory processing are occasionally found as contaminants in blood cultures, on the one hand, and bacteremia occurs asymptomatically in at least 2% of puerperal women, on the other hand. Accordingly, blood culture results must be interpreted in view of organisms present at the infected site (in the case of intra-amniotic infection, the amniotic fluid) and in view of the clinical course.

No previous work has systematically assessed mycoplasmemia in intra-amniotic infection (or clinical chorioamnionitis), but several reports have investigated bloodstream invasion by mycoplasmas in the puerperium. Like bacteria found in the lower genital tract, mycoplasmas have been found at least transiently in the bloodstream immediately after delivery. In 1975, McCormack et al.[8] recovered genital mycoplasmas from 26 of 327 (8%) asymptomatic women within a few minutes after vaginal delivery (*M. hominis* was recovered from 10, *U. urealyticum* from 15, and both from one). These episodes were transient even without specific antibiotic therapy. Of 21 women with mycoplasmemia, 20 (95%) had negative blood cultures upon repeat testing one or more days later. *M. hominis* was isolated from the vaginal culture of nine of 10 (90%) women with this organism in the blood, and *U. urealyticum* was found in the vaginal culture of 10 of 13 (77%) women with ureaplasmemia. Fever after delivery developed in five of 10 (50%) women whose blood contained *M. hominis*, six of 15 (40%) women whose blood contained *U. urealyticum*, and 90 of 301 (30.9%) women whose blood did not contain mycoplasmas (NS). Thus isolation of genital mycoplasmas in blood immediately after delivery was not significantly associated with puerperal fever. Interestingly, four of six women with *M. hominis* in the bloodstream showed a significant rise in mycoplasmacidal antibody titer to homologous isolates whereas none of seven with *U. urealyticum* in the bloodstream showed a serologic response.

There have also been many reports of *M. hominis* in the blood of women with postpartum fever (>24

‡Change equals convalescent minus acute.

hours after delivery). Since 1968, 25 cases have appeared.[9-11]* Available data reveal a mean maximum temperature of 102.7° F. Most patients had no other symptoms noted, and none appeared toxic. Without specific antibiotic therapy, the fever lasted for a mean of 5 days. In six cases, paired antibody studies have been done, and a serologic response was seen in all.[9, 10] At Boston City Hospital, *M. hominis* is isolated from blood of 5% to 10% of women with fever after delivery.[8, 9]

It is also important to note the absence of *M. hominis* from the blood of normal puerperal patients. From four studies including approximately 200 women, *M. hominis* was isolated in the blood of only one patient who, interestingly, showed an antibody response.[8, 9]

U. urealyticum has been noted in the blood of fewer women with postpartum fever. Two cases from Israel were in women who had multiple symptoms, including pneumonia and diarrhea in one and sore throat and myalgia in the other.[12, 13] Eight additional cases were reported from one series (see below).[11] Serologic studies were not performed in any of these cases.

Recently, Lamey et al.[11] reported the largest series of symptomatic puerperal women with mycoplasmemia. Among 125 women with fever (>38° C) at any time after delivery, *M. hominis* was isolated in the bloodstream of nine (7.2%), *U. urealyticum* in eight (6.4%), and bacteria in 15 (12%). In five of these cases, bacteria and mycoplasmas were both isolated from the bloodstream. Blood cultures were also collected from 60 afebrile women 1 or 2 days post partum. None contained genital mycoplasmas. The difference in isolation rate of genital mycoplasmas in the blood between febrile and afebrile women was significant ($p < 0.005$). Of 16 women whose postpartum blood contained mycoplasmas, five (31%) had fever during labor, but three of these five women had simultaneous bacteremia. Fever during labor was significantly associated with organisms in the postpartum blood sample ($p < 0.005$).

Our study compared the rate of intrapartum mycoplasmemia in 81 women with clinical intra-amniotic infection and in 44 asymptomatic women. Although the groups were similar in several characteristics and both had prolonged rupture of the membranes, the intra-amniotic infection group had significantly longer rupture of the membranes, labor, and duration of internal fetal monitoring and a significantly higher cesarean section rate. Despite these differences, there was no significant difference in the rate of isolation of *U. urealyticum* in maternal blood. Isolation of *M hominis* in maternal blood was found only in the intra-amniotic infection group, but this occurred infrequently (2%) and was not significantly different from the rate in the asymptomatic group. Our overall rate of mycoplasma isolation in maternal blood in cases of intra-amniotic infection (16.0%) is similar to that observed by Lamey et al.[11] (13.6%) in maternal blood in cases of puerperal fever. Whereas those authors found *M. hominis* in 7.2% of blood cultures and *U. urealyticum* in 6.4%, we found *U. urealyticum* more commonly (13.6%) and *M. hominis* less commonly (2.5%). However, the major difference in observations is that Lamey et al. found no cases of mycoplasmemia among 60 asymptomatic puerperal women in contrast to our observation of frequent ureaplasmemia in asymptomatic women. This discrepancy may be explained by our asymptomatic group being in labor and the control group of Lamey et al. being postpartum. It is pertinent that McCormack et al.[8] found mycoplasmas in the blood transiently after delivery. Within 2 minutes, 15% had mycoplasmemia, but more than 10 minutes after delivery, only 2% had myco-

*A complete list of references will be sent to the reader on request.

*Results of amniotic fluid cultures.

†Change equals convalescent minus acute.

plasmemia. Thus ureaplasma may be recovered transiently from the bloodstream of women in labor, at least in a group with prolonged membrane rupture.

When *M. hominis* was found in the blood, it was also found in the amniotic fluid. When *U. urealyticum* was found in the blood, it was isolated in the amniotic fluid in 16 of 19 cases (84%). Similarly, McCormack et al. found ureaplasma in the vagina in 77% of women whose blood contained this organism in the immediate puerperium.[8] These discrepancies may result from false negative amniotic fluid culture or from *U. urealyticum* having another portal of entry (for instance, the dilating cervix).

Neonatal blood cultures were subcultured for mycoplasmas as recommended by Caliando and McCormack,[5] but none was isolated. It is unclear whether this observation results from loss of organisms during culture or lack of invasiveness of genital mycoplasmas in the neonate. Mycoplasmas have been isolated from the blood of 7% of spontaneously aborted fetuses, but mycoplasmas were not isolated from neonatal blood, cerebrospinal fluid, or the interior of tissues at autopsy at Boston City Hospital.[14]

The second part of our study assessed serologic response to genital mycoplasmas in paired sera. An increase in specific antibody production is often taken as evidence of pathogenicity of an organism in a particular disease, yet, as with blood culture isolation, serologic techniques also have their limitations. A rise in antibody titer is usually indicative of recent exposure to antigen but is unable to indicate clinical disease or to localize the site of infection.

Serologic studies have not been previously performed in cases of clinical intra-amniotic infection (or clinical chorioamnionitis), but serologic investigations have been performed in patients with postpartum fever. In addition to the few serologic studies in reports of mycoplasmemia,[9, 10] the only other pertinent serologic data came from a recent survey at Boston City Hospital. Of 535 women who had vaginal deliveries, 23 had postpartum fever with no extragenital explanation.[15] A mycoplasmacidal antibody response to *M. hominis* was observed in 10 (44%). The strongest single predictor of these so-called "unexplained fevers" was an absent or low titer of antibody against *M. hominis*.

In the present study, we compared serologic response to *M. hominis* and to *U. urealyticum* in 50 women with intra-amniotic infection and in 33 asymptomatic control subjects. We used an enzyme-linked immunosorbent assay technique, which is rapid, reliable, and specific. As with blood culture data, the intra-amniotic infection patients in this part of the study had significantly longer labors, longer intervals from rupture of the membranes to delivery, and more cesarean deliveries. These potential confounding variables may have influenced the serologic results.

For *M. hominis*, the antibody response in patients with intra-amniotic infection and amniotic fluid positive for *M. hominis* is significantly different from patients with intra-amniotic infection and amniotic fluid negative for *M. hominis* and from control patients with negative amniotic fluid. *M. hominis* occurs infrequently in amniotic fluid of asymptomatic patients, although the response in these patients resembles that of the intra-amniotic infection group with *M. hominis* in amniotic fluid. It is not yet known whether there are responses to other organisms isolated in the amniotic fluid. It is also unclear why we detected a serologic response (mainly by "seroconversion") in some patients with amniotic fluid negative for *M. hominis*. Possibly these apparent seroconversions represent antigen exposure from the cervix. It is also possible that a small absolute difference in enzyme-linked immunosorbent assay reading may lead to a change, for example, from a negative to a weakly reactive value. These limitations of serologic techniques and of enzyme-linked immunosorbent assays are well recognized.

Although the intra-amniotic infection and control

groups were significantly different (labor, rupture of the membranes, cesarean section rate, etc.), we believe that these potential confounding variables have not influenced the serologic data for *M. hominis*. Indeed, we have demonstrated that route of delivery was not associated with serologic response and response was strongly associated with the presence of the organism and not simply with intra-amniotic infection.

For *U. urealyticum*, a different pattern was seen. Here the antibody response was significantly greater in the intra-amniotic infection group, but there was no difference between those with and without *U. urealyticum* in the amniotic fluid. This response is more difficult to interpret but may arise from (1) false negative amniotic fluid cultures for *U. urealyticum*, (2) antigen exposure from a site other than the amniotic fluid, or (3) lack of assay specificity. The first two possibilities are likely to make some contribution, as we saw negative amniotic fluid cultures for *U. urealyticum* in 15% (16 of 19) of women whose blood contained this organism. Manganese is present in Shepard's A,B agar, which was used for culture in the last part of the study. Robertson and Chen[16] have recently found that low concentrations (1 mmol/L) of manganese cation inhibited the growth of all standard strains of *U. urealyticum* to varying degrees. Perhaps use of manganese-containing agar contributed to false negative cultures of amniotic fluid. Assay specificity for *U. urealyticum* has been addressed previously.[6] Evidence supporting a high specificity includes excellent agreement with the metabolic inhibition assay (82% to 95% agreement in sera of patients with nongonococcal urethritis) and lack of cross-reactivity of *U. urealyticum* antigen with rabbit antisera of *M. hominis* or other mycoplasma species.

Our serologic data in the two women whose blood contained *M. hominis* is consistent with previous observations showing a nearly universal antibody response. In patients with ureaplasmemia, we saw an antibody response in one of two women with intra-amniotic infection and neither of two control women. The only other pertinent observation is that of McCormack et al., who observed no responses in any of seven women with transient ureaplasmemia after vaginal delivery. It was not noted whether any of these seven patients developed fever in the puerperium.

In sum, when *M. hominis* was found in the amniotic fluid or maternal blood, the patient was nearly always symptomatic. The high likelihood of serologic response in these patients lends further support to the pathogenicity of *M. hominis* in intra-amniotic infection. These observations parallel those in women with puerperal fever. When *U. urealyticum* is found in amniotic fluid or blood, patients are commonly asymptomatic. Although the pattern of serologic response is strongly associated with intra-amniotic infection, it is not associated with isolation of *U. urealyticum*. The observation that some patients with intra-amniotic infection have both ureaplasmemia and a serologic response supports the view that in these patients *U. urealyticum* is pathogenic. However, its pathogenicity in most cases of intra-amniotic infection remains unclear.

We express our gratitude to Lynn Duffy for excellent technical assistance.

Discussion

Dr. Richard H. Schwarz, Brooklyn, New York. Dr. Gibbs and his colleagues continue to pursue the role of genital mycoplasmas in obstetric infection. In their earlier study[1] they demonstrated that *M. hominis* could be isolated more frequently from amniotic fluid in patients with intra-amniotic infection than in that of control subjects. However, in that study as well as the current one there was a significant isolation of high-virulence bacteria in the intra-amniotic infection patients as well. Blood cultures in the current study were positive for *M. hominis* in only two patients, as compared to none of the control subjects, and although an interesting finding this is not statistically significant. The authors have attempted to further establish the significance of *M. hominis* by measuring serologic reactions. They have shown that serologic responses were more common in patients with *M. hominis* in amniotic fluid and intra-amniotic infection (70%) than in patients with intra-amniotic infection who did not have *M. hominis* in amniotic fluid (30%). Unfortunately, serologic responses also occurred in a significant percentage of those patients with positive amniotic fluid culture for *M. hominis* who did not manifest intra-amniotic infection (67%). All of this prompts a basic question: Has the study really established a pathogenic role for *M. hominis* in intra-amniotic infection? If so, is that role as a primary pathogen or does it act synergistically with the high-virulence bacteria so commonly present?

The data with regard to *U. urealyticum* are more difficult to interpret. Although recovery of this organism from amniotic fluid and blood was relatively common in asymptomatic women, seroconversion was significantly associated with intra-amniotic infection in the absence of *U. urealyticum* isolation. The authors have offered several explanations for this seeming disparity, concentrating for the most part on false negative amniotic fluid cultures.

Since the mycoplasmas are found so frequently in the vagina of asymptomatic women, it is not surprising that they have been implicated in a variety of reproductive problems from infertility to pelvic inflammatory disease to obstetric infections. Local recovery of the organism therefore does not establish a pathogenic role, and consequently further studies such as this are necessary to clarify that matter.

There are several questions I would like to pose for Dr. Gibbs.

1. Would it be possible to control for factors such as length of labor, duration of rupture of membranes, and intrauterine monitoring? The control subjects differed in all of these categories and it is possible that the rate of amniotic fluid recovery of mycoplasmas might be higher (even without intra-amniotic infection) after a longer exposure.

2. Serologic results were measured in three different ways. Would the results have differed if only strict seroconversion had been the criterion?

3. The authors suggest that mycoplasma seroconversion in patients without intra-amniotic infection may be the result of responses to cervical organisms. Are any data available on vaginal or cervical cultures in the study populaton?

4. The absence of *M. hominis* antibody has been shown to be predictive of postpartum fever. Is it also predictive of intra-amniotic infection?

5. In our own studies[2] of vaginal organisms in relation to other adverse pregnancy outcomes, namely, preterm delivery, mycoplasma was found to be associated with other significant organisms by analysis of covariance. Is a similar association possible in this study as well?

Dr. Rudolph P. Galask, Iowa City, Iowa. I have three questions that I would like to ask.

Were the control women and the patients who subsequently developed endometritis evaluated?

The second question is when were the blood cultures obtained? Was this timed with fever in the subjects, and when were blood cultures obtained in the control women?

Were these done singly, in duplicate, or in triplicate?

The third question is how was the purification of the antigen done, and how did the authors determine specificity for the enzyme-linked immunosorbent assay technique described?

Dr. Kamran S. Moghissi, Detroit, Michigan. As Dr. Schwarz mentioned, the *U. urealyticum* has been incriminated in both infertility and repeated abortion.

My question is whether the previous reproductive histories of these women were known. Also can Dr. Gibbs speculate as to whether a positive serologic result might, in fact, have predated the current pregnancy?

Dr. Gibbs (Closing). I would like to thank Dr. Schwarz for his careful review of our work.

This certainly has been a complex topic considering the polymicrobial nature of this infection.

To his first question, that is, could we have controlled for those obstetric variables that were different between the symptomatic and asymptomatic groups, I would respond by saying that this would have been preferable, and, in fact, this was a technique that we used when we were analyzing the amniotic fluid microbiology, not for mycoplasmas only but for bacteria. We used patients who were matched with regard to those obstetric variables.

In these current studies there were significant differences in several obstetrical variables, and let me try to address how those differences might or might not have influenced the results.

Despite the differences, there were no significant differences in isolation of *U. urealyticum* from maternal blood. Isolation of *M. hominis* was found only in the blood of women with intra-amniotic infection, but the difference was not significant either. Thus I would not anticipate that controlling for those obstetric variables would have influenced the results.

In the serologic group of patients, there were again significant differences in those obstetric variables, but here I do not believe that those differences influenced the results. First of all, all sera were collected within a relatively short time of delivery, and the absolute difference, 6 or 12 hours, in those labor and delivery variables, was small compared with the half-life of IgG antibodies.

With regard to Dr. Schwarz' second question of strict seroconversion, we looked at that also. If we define seroconversion as a change from a negative value to a reactive value, then the distribution looks quite similar to the response of patients with a rise >0.2 optical density units.

The third question was do we have data on the vaginal and cervical cultures in this study population?

At the time we were performing this study, we were not doing concomitant vaginal and amniotic fluid cultures. We do know from a group of similar women in our obstetric population that ureaplasma and *M. hominis* occur more commonly, of course, in the lower genital tract than in the amniotic fluid, and currently we isolate *M. hominis* about 35% overall in the lower genital tract and ureaplasma about 60% overall.

The fourth question was whether the absence of antibodies to *M. hominis* is predictive of the development of intra-amniotic infection in view of observations by Platt et al. in Boston that absence of *M. hominis* antibodies was the most significant predictor of the development of postpartum fever.

We found no significant difference in the mean acute absorbance across the four groups.

I point out that Platt et al. used a mycoplasmachidal antibody titer and we used an enzyme-linked immunosorbent assay technique.

Although previous studies done by Cassell et al. have shown a good correlation between these two techniques, we did not find that a lower ELISA reading was predictive of intra-amniotic infection.

Dr. Schwarz' fifth question was: Is *M. hominis* associated with organisms that we have labeled high-virulence organisms in the amniotic fluid? In both this series and our original work, we found a high association between the presence of *M. hominis* and these high-virulence bacteria.

Here more than 75% of amniotic fluid samples with *M. hominis* also had 10^2 cfu/ml of high-virulence bacteria, and currently we are investigating the serologic response to these other common bacteria in amniotic fluid.

Dr. Galask asked whether we excluded patients who were asymptomatic in labor and who subsequently developed endometritis. Yes, they were excluded, and we also excluded patients who had transient postpartum fever.

One set of blood cultures for mycoplasma was collected during labor in the intra-amniotic infection group from patients who were febrile at the time. The sample was collected from control patients at the time that an amniotic fluid sample was obtained. This generally meant patients in labor with 10 to 12 hours of membrane rupture.

Dr. Galask's last question had to do with how the antigen was prepared, and how we tested for specificity since that is a question in particular with regard to the ureaplasma data.

The antigen was prepared from a whole cell lysate of *M. hominis* and *U. urealyticum* prepared with bicarbonate buffer and adherent to the plastic wells.

We looked very hard at the data, especially with regard to ureaplasma and questioned specificity. In previous work by Dr. Cassell the question of specificity was addressed in two ways.

First, there was a comparison between the mycoplasmacidal titer and the enzyme-linked immunosorbent assay response, and the agreement was good, generally between about 85% and 95%.

The other way that the assay specificity was compared was to look at the antigen preparation compared with known hyperimmune sera against other mycoplasma species. There again there was very little to suggest lack of assay specificity.

Dr. Moghissi asked whether we had information on the previous reproductive history of these patients. The majority of patients in both groups were young and nulliparous.

Could it be that the positive serologic result predated pregnancy? Yes, especially with regard to ureaplasma. We had a high level of reactivity in the serum in nearly all of our patients. This was a common antigen that our patients were exposed to.

With regard to *M. hominis* antigen, positivity was less common but still present in a considerable percentage of our patients.

The effects of enclomiphene and zuclomiphene citrates on mouse embryos fertilized in vitro and in vivo

Grant E. Schmidt, M.D., Ph.D., Moon H. Kim, M.D., Ragaa Mansour, M.D., Lynne Torello, M.D., and Chad I. Friedman, M.D.

Columbus, Ohio

The ovulatory agent clomiphene citrate, a racemic mixture of the estrogenic zuclomiphene and antiestrogenic enclomiphene isomers, has been associated with gamete/embryo toxicity in various animal models. To assess the potential effects of these isomers on fertilization and early embryogenesis, 3200 embryos were obtained from mouse oocytes fertilized in vivo and in vitro and exposed to increasing concentrations of zuclomiphene, enclomiphene, and clomiphene citrate in culture. Fertilization rates ($p < 0.01$), blastocyst formation rates ($p < 0.02$), and degeneration rates ($p < 0.005$) were all adversely affected in a dose-dependent fashion. There were no statistically significant differences between the two isomers. Preincubation with 17β-estradiol did decrease the degenerative changes induced by clomiphene citrate but did not improve the decreased rate of blastocyst formation. These findings suggest adverse effects of a high concentration of clomiphene citrate and its isomers on fertilization and early mouse embryo growth that may have implications in the clinical use of this drug. (AM J OBSTET GYNECOL 1986;154:727-36.)

Key words: Clomiphene citrate, embryo toxicity, in vitro fertilization

Clomiphene citrate, a nonsteroidal triphenylethylene compound, is probably the most common agent used for induction of ovulation presently in medical use. Orally active, the drug is composed of two isomers, enclomiphene and zuclomiphene, formerly named cis-clomiphene and transclomiphene. Clomiphene citrate has a reported 60% to 80% ovulation rate and an associated 40% to 50% pregnancy rate, but there may also be an increased rate of spontaneous abortion associated with the use of clomiphene citrate.[1,2] The relative potencies of the two isomers in inducing ovulation in the human is unknown; however, in animal studies it appears that zuclomiphene is the more estrogenic of the two, although significant discrepancies do exist.[3-5] While the two marketed compounds (Clomid and Serophene) differ in their percent composition of the isomers, the clinical ovulation rate is reported to be unchanged.

Clomiphene citrate binds to the cytoplasmic estrogen receptor in numerous tissues including the hypothalamus, pituitary, and ovary.[5,6] It is thought to function by releasing the inhibitory effect of endogenous estrogens on gonadotropin secretion, possibly by alterations in gonadotropin-releasing hormone patterns. However, the precise mode of action in the hypothalamic-pituitary axis has yet to be determined. The evidence is clear, however, that clomiphene citrate may act as an estrogen or antiestrogen in the human, depending on the clinical situation when administered.[6] While the effects of the separate isomers zuclomiphene and enclomiphene have not been well studied in the human, most reports associate zuclomiphene with primarily estrogenic effects and enclomiphene with antiestrogenic activities.[3] It is interesting therefore that zuclomiphene citrate is considered to be the active isomer in clomiphene citrate when used for induction of ovulation.

At the ovarian level, clomiphene citrate has also been reported to have both estrogenic[7] and antiestrogenic[8] activity, and this again may correspond to the differential activity of the two isomers. Little is known of the effects of clomiphene citrate on the developing oocyte or on early embryogenesis. Early studies had suggested degenerative changes in oocytes and embryos in animals exposed to clomiphene citrate immediately after ovulation and that this damage was not reversed with estrogen administration.[9-11] More recently there have been contradictory findings of complete reversal of the effects of clomiphene citrate administered to mice before ovulation by concomitant administration of 17β-estradiol.[12] In another recent study using ovarian perfusion techniques, clomiphene citrate induced increased oocyte degeneration.[13] Decreased development of two-cell mouse embryos has also been reported from mouse oocytes pretreated with clomiphene citrate be-

From the Department of Obstetrics and Gynecology, The Ohio State University Hospitals.

Presented at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.

fore in vitro fertilization, but it is interesting that embryo growth from the two-cell embryo to the blastocyst stage was unaffected.[12] Unfortunately, the fertilization rate in the control groups was relatively low and the short pretreatment period may not accurately reflect the in vivo situation. No data are available on the effects of either zuclomiphene or enclomiphene citrate on the oocyte or embryo.

Considering the widespread clinical use of clomiphene citrate and the limited amount of data concerning the effects of the racemic mixture on either the fertilization process or early embryogenesis, it was of considerable interest to pursue the potential toxicity studies. The approach was to eliminate possible in vivo influences by exposing mouse oocytes fertilized either in vivo or in vitro to clomiphene, zuclomiphene, or enclomiphene citrate in an in vitro culture system, observing the rates of fertilization, embryo growth, and embryo degeneration. The findings suggest that there is a sensitivity to both clomiphene and its isomers from the time of fertilization until the two- to four-cell stage, which results in increased embryo degeneration and decreased cell growth. These alterations are sometimes not apparent until 24 to 48 hours after exposure and are not reversed with estrogen treatment.

Material and methods

Culture media. Hams F-10 with glutamine (Gibco Laboratories, Grand Island, New York), supplemented with calcium lactate, 0.8 mmol/L; sodium bicarbonate, 20 mmol/L; potassium bicarbonate, 5 mmol/L; penicillin, 100 IU/ml, and streptomycin, 100 IU/ml (Sigma Chemical Co., St. Louis, Missouri), was adjusted to an osmolarity of 278 ± 2 mosm/L and used as the primary culture medium. Heat-inactivated preovulatory human serum (56° C for 30 minutes) was added, 7.5% for the fertilization media and 15% for the growth media. The mixture was adjusted to pH 7.4 after equilibration with 5% carbon dioxide/5% oxygen/90% nitrogen and filter sterilized immediately before use. All cultures were carried out in welled Falcon culture dishes (Becton Dickinson Co., Oxnard, California) in a humidified 5% carbon dioxide/air incubator at 37° C.

Clomiphene, enclomiphene, and zuclomiphene citrates in powdered form were a gift from Merrell Dow Pharmaceuticals. A stock solution of clomiphene and each isomer was prepared by dissolving 3.0 mg of the citrate in 10 ml of culture media. All experimental oocytes or two-cell embryos were exposed for at least the first 24 hours of culture to clomiphene-, enclomiphene-, or zuclomiphene-supplemented media with subsequent transfer to drug-free growth media after 24 hours.

Animals. Female CB_6F_1 mice (Jackson Labs, Indianapolis, Indiana), 10 to 15 weeks of age, were used in all experiments. This hybrid is a cross between the Balb/c and C57B1/6 strains and consistently has provided oocytes with greater than 90% in vitro fertilization rates in our laboratory. Male mice were of the CD-1 strain (Jackson Labs), 8 to 10 months old, and had proved fertility. Ovulation induction was carried out by standard methods. On the first day of estrus determined by vaginal smear, the female mouse was administered 7.5 IU of pregnant mare serum gonadotropin (PMSG) intraperitoneally followed by 7.5 IU of human chorionic gonadotropin (hCG) intraperitoneally 72 hours later.

In vitro fertilization. The female mice were put to death by cervical dislocation 14 to 16 hours after the hCG injection. Oviducts were removed and the cumulus mass in each was dissected free. The oocytes were dispersed from the cumulus cells with 0.1% hyaluronidase. In most experiments oocytes from four mice were pooled and then randomly distributed into the control or experimental groups for subsequent fertilization.

The male mice were put to death by cervical dislocation and both epididymides were placed in unsupplemented culture media. Each epididymis was cut into six to eight pieces and incubated in 5% carbon dioxide/air at 37° C for 30 minutes. This cultured suspension was then filtered through gauze, the supernatant sperm suspension centrifuged at 150 × g for 7 minutes, and the pellet resuspended in 2 ml of culture media. Sperm motility and count were then evaluated and 0.5×10^6 motile sperm added to each dish containing eight to 10 oocytes. The ova and sperm were incubated for 24 hours in control or drug-supplemented fertilization media containing 0.1, 1, 10, 25, 50, and 100 μg/ml of clomiphene citrate or 0, 0.1, 0.5, 1, 10, 25, and 50 μg/ml of enclomiphene or zuclomiphene citrate. After 24 hours all fertilized oocytes were transferred into drug-free media. At 24-hour intervals the dishes were examined for fertilization rate, the number of blastomeres per embryo, blastocyst formation, and degenerative changes. At 96 hours, photomicrographs were taken for final evaluation. For each concentration of clomiphene, enclomiphene, and zuclomiphene citrate, 120 to 215 oocytes were tested.

In vivo fertilization. After the hCG injection, a male mouse was caged with each female mouse and left overnight. After mating was confirmed by observation of the vaginal plug, the female mice were put to death by cervical dislocation 24 to 26 hours after hCG administration. The oviducts were then excised and the fertilized ova were extracted and placed in growth media at 37° C. In most experiments, fertilized oocytes from four to six mice were pooled and then randomly distributed. A minimum of 100 oocytes were included in each group tested.

Clomiphene citrate–supplemented growth media containing 0, 0.1, 1, 10, 25, 50, and 100 μg/ml of the

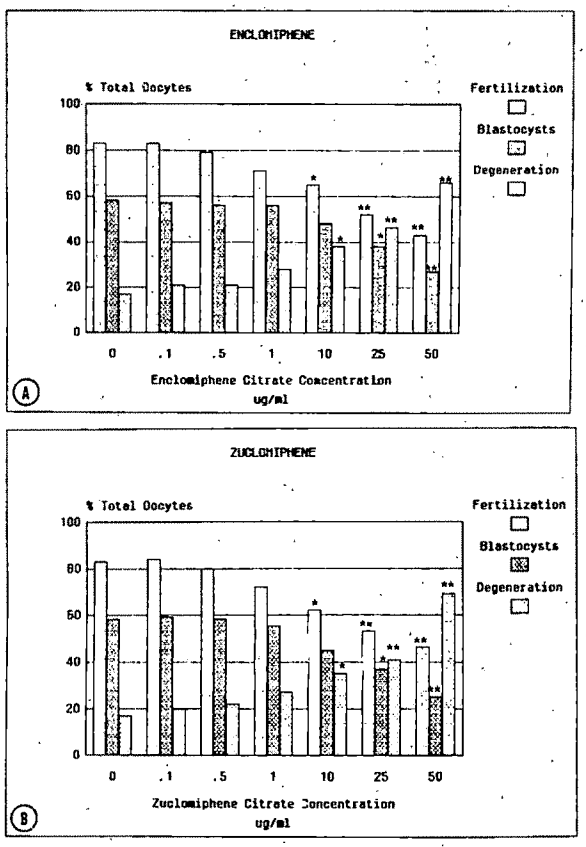

Fig. 1. *A*, The effects of enclomiphene citrate on the development of mouse oocytes fertilized in vitro. The oocytes were exposed to 0 to 50 μg/ml of enclomiphene citrate in culture media for the first 24 hours of the 96-hour incubation. Each group consists of 120 to 215 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.) *B*, The effects of zuclomiphene citrate on the development of mouse oocytes fertilized in vitro. Conditions are identical to those in *A* except for the drug. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.)

drug and enclomiphene and zuclomiphene citrate–supplemented media containing 0, 0.1, 0.5, 1, 10, 25, or 50 μ/ml of the drug were used as the incubation media for 24 hours followed by transfer to unsupplemented growth media. At 24-hour intervals the embryos were examined for blastocyst formation; the number and morphology of the blastomeres were also noted. At 72 hours, photomicrographs were taken of the embryos for final evaluation. In studies evaluating exposure to clomiphene citrate for 72 hours, the embryos were transferred every 24 hours into media containing 0.1, 1, and 10 μg/ml of clomiphene.

Statistical analysis was performed with the test of proportions with z score.

Results

In vitro fertilization. Mouse oocytes were exposed to increasing concentrations of zuclomiphene citrate, enclomiphene citrate, and clomiphene citrate, ranging from 0 to 100 μg/ml during the fertilization process.

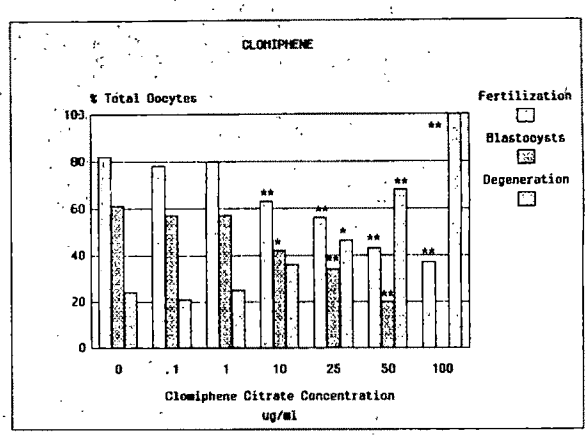

Fig. 2. Effects of clomiphene citrate on the development of mouse oocytes fertilized in vitro. The oocytes were exposed in culture to 0 to 100 μg/ml of clomiphene citrate for the first 24 hours of the 96-hour incubation. Each group consists of 100 to 250 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.)

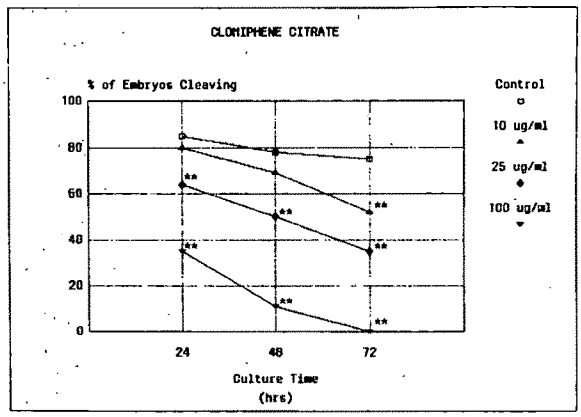

Fig. 3. The rate of progressive mouse embryo cleavage after in vitro fertilization and clomiphene citrate exposure. The oocytes have been exposed in culture to 0 to 100 μg/ml of clomiphene citrate for the first 24 hours. Each group consists of 100 to 250 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.)

The fertilization rate of the untreated oocytes, based on achieving a two-cell embryo, was 83%. Fig. 1 summarizes the results comparing the rates of oocyte fertilization, embryo growth as assessed by blastocyst formation, and degeneration where exposed to enclomiphene (Fig. 1, *A*) and zuclomiphene (Fig. 1, *B*) citrates in the culture media. For comparison, Fig. 2 summarizes the same situation with a racemic mixture of clomiphene citrate.

As noted with both the racemic mixture and the isomers, the fertilization rate and the embryo growth rate both declined in a dose-dependent fashion as the drug concentration increased. These changes reached statistical significance ($p < 0.05$) at a concentration of 10 μg/ml. There was no statistically significant difference between the two isomers in either fertilization rates or

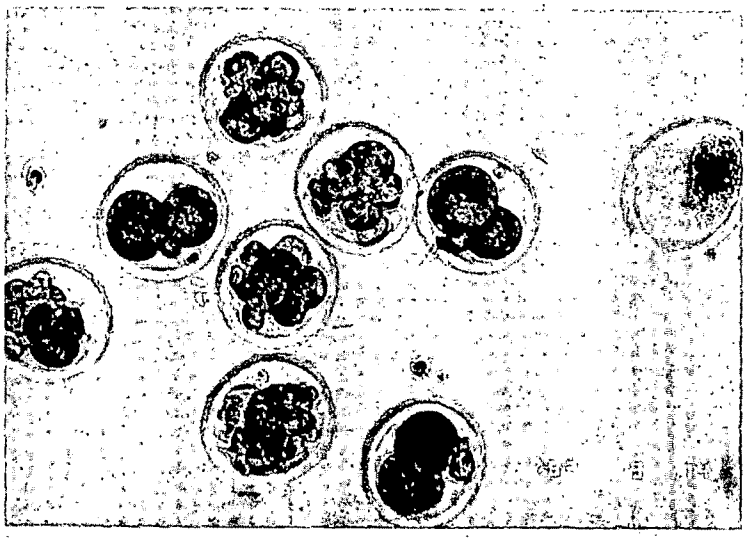

Fig. 4. The effect of enclomiphene citrate exposure on cultured mouse embryos. These embryos fertilized in vitro were exposed to 25 μg/ml of enclomiphene citrate 43 hours previously and are representative of degenerated cells. (Original magnification × 300.)

Table I. Degeneration of 4- to 8-cell mouse embryos with exposure to enclomiphene and zuclomiphene citrate

blastocyst formation rates. As seen in Fig. 3, the rate of progressive embryo cleavage was detectably slower as early as 24 hours with clomiphene citrate concentrations ≥25 μg/ml and became more pronounced after each additional 24 hours. The actual percent of two-cell embryos reaching the blastocyst stage decreased with the increasing concentrations of either the racemic clomiphene citrate or its isomers from 68% to 72% in nontreated culture to 0% at 100 μg/ml concentrations.

The embryo degeneration rate also demonstrated a dose-dependent ratio but increased with increasing drug concentrations. This occurred in both the racemic clomiphene citrate and the isomers enclomiphene citrate and zuclomiphene citrate. Embryos were not classified as degenerated unless the structural alternatives were visible at low microscope power and consisted of primarily pyknotic nuclei that had retracted from the zona pellucida and multiple blebs from the blastomeres. Arrested growth of the embryo was not classified as degeneration until the cellular changes were visualized. An example of degenerated embryos exposed to 25 μg/ml of enclomiphene are seen in Fig. 4.

100	15	15	100†

*$p < 0.05$ versus control value.
†$p < 0.001$ versus control value.

Degeneration of embryos reaching the four-cell stages was more frequent in embryos that had been exposed to either zuclomiphene or enclomiphene citrate than in the nontreated group, reaching significance at concentrations >10 μg/ml (Table I). There was no statistical difference between the two isomers in their effects on delayed embryo degeneration. In separate studies, clomiphene citrate demonstrated similar findings, as seen in Table II.

In vivo fertilization. To minimize the potential effect of clomiphene or the isomers on the fertilization process as the primary embryo-toxic effect, two-cell embryos were obtained from mice after natural mating

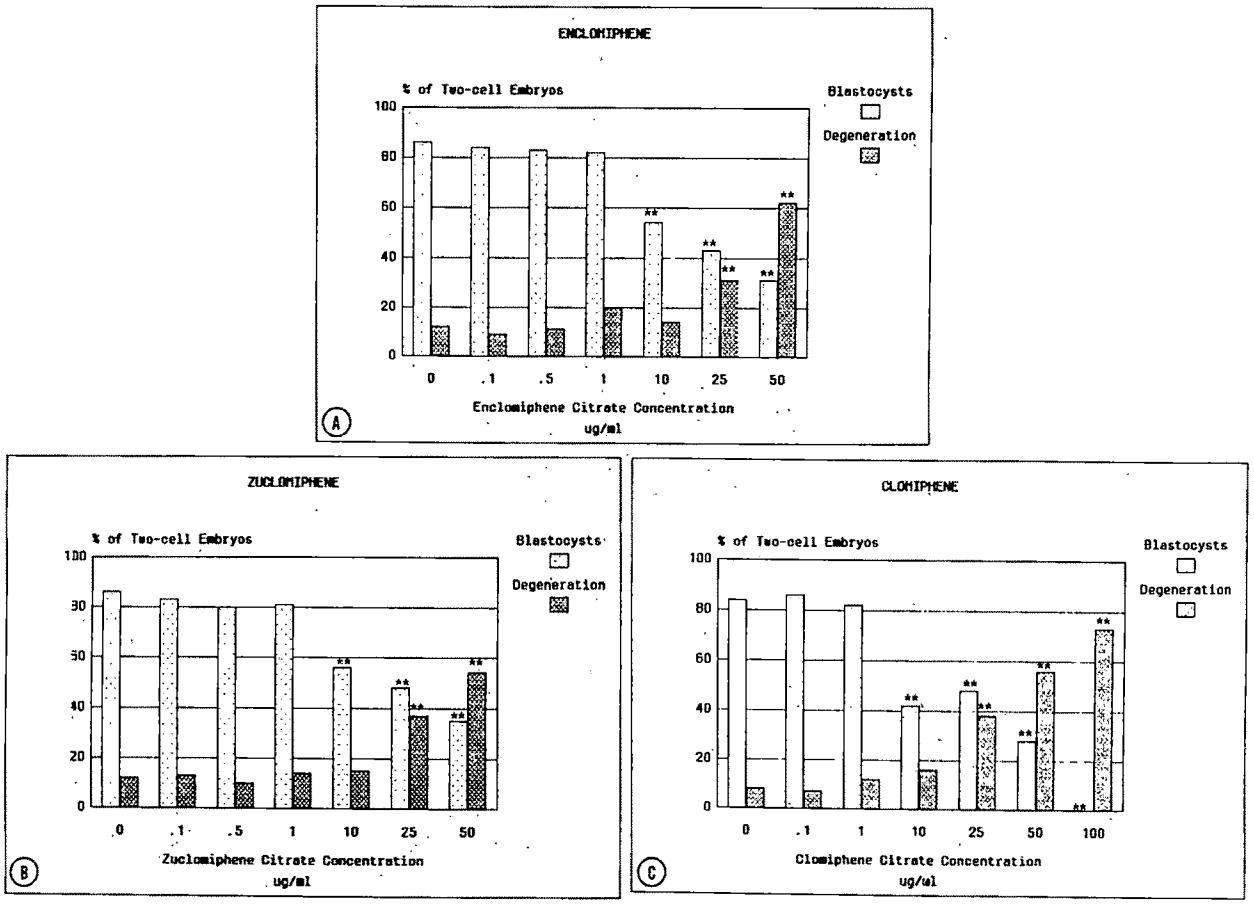

Fig. 5. *A*, The effects of enclomiphene citrate on the development of mouse oocytes fertilized in vivo. The fertilized oocytes underwent a 24-hour exposure to 0 to 50 μg/ml of enclomiphene citrate in the culture media. Each group consists of 100 to 180 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.) *B*, The effects of zuclomiphene citrate on the development of mouse oocytes fertilized in vivo. The fertilized oocytes underwent a 24-hour exposure to 0 to 50 μg/ml of zuclomiphene citrate in the culture media. Each group consists of 100 to 180 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.) *C*, The effects of clomiphene citrate on the development of mouse oocytes fertilized in vivo. The fertilized oocytes underwent a 24-hour exposure to 0 to 100 μg/ml of clomiphene citrate in culture media. Each group consists of 100 to 150 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.)

and exposed to zuclomiphene, enclomiphene, and clomiphene citrates for the first 24 hours of culture. Blastocyst formation was determined at 72 hours; in the untreated group 86% of the two-cell mouse embryos reached the blastocyst stage during that time. Degeneration of the embryos in the untreated groups during the same time period was 12%.

Embryos resulting from oocytes fertilized in vivo and exposed to enclomiphene (Fig. 5, *A*), zuclomiphene (Fig. 5, *B*), or clomiphene citrate (Fig. 5, *C*) in culture media demonstrated findings similar to those of the oocytes fertilized in vitro. There was a significant decrease in the blastocyst formation beginning at a drug concentration of 10 μg/ml ($p < 0.01$) in all three drug groups. Again, there was no significant difference between the two isomers in the decreased blastocyst formation rate. There were no blastocysts formed in the clomiphene citrate–treated group at a concentration of 100 μg/ml ($p < 0.001$). Growth rates, the percent of embryos that have divided at 24-hour intervals, is shown in Fig. 6. Enclomiphene and zuclomiphene citrate appear to alter growth rates beginning at 10 μg/ml at 48 hours.

An interesting observation is the lack of significant change in the number of degenerating embryos at the 10 μg/ml concentration of either enclomiphene or zuclomiphene. This results from increased numbers of drug-exposed embryos undergoing maturation arrest but not degenerating.

To determine whether additional exposure (>24

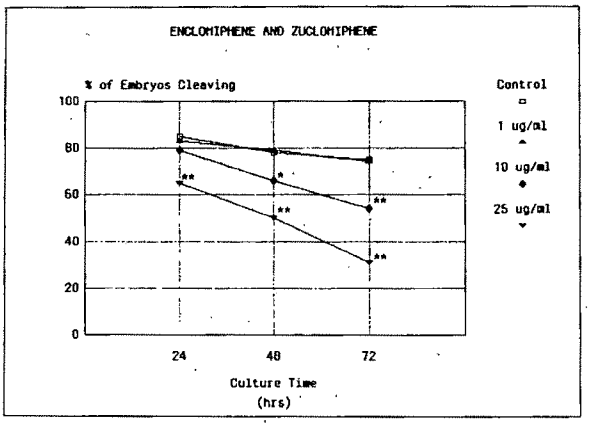

Fig. 6. The rate of progressive mouse embryo cleavage after in vivo fertilization and enclomiphene and zuclomiphene citrate exposure. The fertilized oocytes were exposed to 0 to 50 μg/ml of either enclomiphene or zuclomiphene citrate for the first 24 hours of culture. Each group represents pooled results of the individual isomers and consists of 180 to 260 oocytes. (* = $p < 0.01$ versus control value; ** = $p < 0.001$ versus control value.)

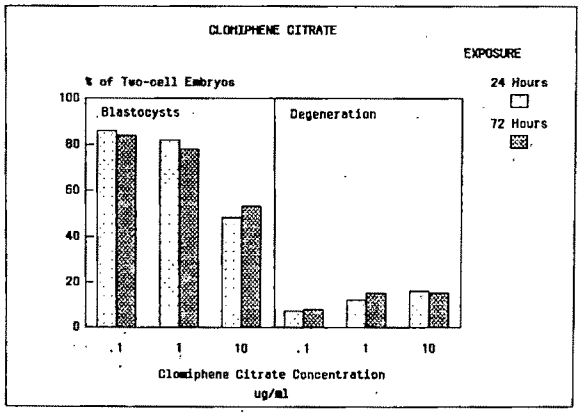

Fig. 7. The effect of length of clomiphene citrate exposure on the development of mouse oocytes fertilized in vivo. The fertilized oocytes were exposed to 0.1, 1, and 10 μg/ml of clomiphene citrate for 24 and 72 hours. Each group consists of 100 to 150 oocytes. There were no significant differences between the groups.

hours) of the cultured embryos to clomiphene citrate had any additional effect, two-cell embryos were exposed to 0.1, 1, and 10 μg/ml of clomiphene citrate for the entire 72-hour culture period (Fig. 7). There does not appear to be any additional effect in terms of blastocyst formation or embryo degeneration measured at 72 hours, whether the embryos are exposed for 24 or 72 hours.

To assess whether exposure of the mouse two-cell embryo to 17β-estradiol would ameliorate or prevent the embryo-toxic effects of clomiphene citrate, 17β-estradiol was added to the culture media at a concentration of 1 and 10 ng/ml for the first 24 hours. As seen in Fig. 8, the addition of the 17β-estradiol had no adverse effect when these embryos were compared with

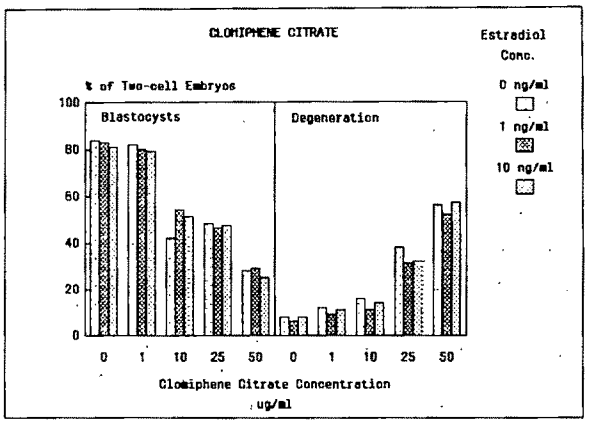

Fig. 8. The effect of concomitant 17β-estradiol treatment to mouse embryos fertilized in vivo and exposed to clomiphene citrate. The fertilized oocytes were exposed to 0 to 50 μg/ml of clomiphene citrate and 0, 1, or 10 ng/m of 17β-estradiol for the first 24 hours of culture, and blastocyst formation and degeneration were assessed at 72 hours.

untreated ones in terms of either blastocyst formation or embryo degeneration, and at clomiphene citrate concentrations of 1, 10, and 25 μg/ml, while there was no significant improvement in blastocyst formation, there was a generalized decrease in degeneration rates where 17β-estradiol was included in the culture media. This trend was not statistically significant. At concentrations >25 μg/ml of clomiphene citrate, concomitant treatment with 17β-estradiol had no effect.

Comment

Clomiphene citrate is a synthetic, nonsteroidal compound widely used as an ovulatory agent in clinical practice and has seen increasing use in in vitro fertilization–embryo transfer programs as a superovulatory agent. A discrepancy between ovulation and pregnancy rates and an increased spontaneous abortion rate during clomiphene citrate therapy has prompted concern over its potential embryo-toxic effects. Clomiphene citrate has been shown to bind to cytoplasmic estrogen receptors in multiple tissues[5,6] and may act as either an estrogen agonist or an antagonist, depending on the site, the estrogen level, and the length of exposure.[6] Since clomiphene is actually a mixture of the isomers zuclomiphene and enclomiphene, which are usually reported to display estrogenic and antiestrogenic activities, respectively,[3] it is of interest to determine whether the isomers display different effects on fertilization and embryo growth when compared with the racemic clomiphene citrate mixture.

The effects of clomiphene citrate at the level of the gamete or early embryo are limited. Early studies suggested degenerative changes in oocytes and embryos from animals exposed to clomiphene citrate after ovulation.[9-11] These effects did not appear to be reversed with estradiol treatment. In a more recent study

with PMSG-hCG–injected mice,[12] preovulatory subcutaneous injection of clomiphene citrate resulted in decreased mating activity and ovulation and delayed embryo development, all of which were reversed with 17β-estradiol. The authors also found a dose-dependent decrease in blastocyst formation and an increase in degenerated and unfertilized ova in mouse oocytes pretreated for 6 hours with clomiphene citrate before in vitro fertilization. They also noted that the growth rate from the two-cell embryo to the blastocyst appeared to be unaffected by the short pretreatment with clomiphene citrate. No data are available on the effects of zuclomiphene or enclomiphene on the ovary, gametes, or early embryos.

Studies that use in vivo exposure to clomiphene citrate have several potential limitations. Clomiphene does not induce ovulation in most animal species,[3] and depending on the tissue and species, both clomiphene and the individual isomers may act as either estrogens or antiestrogens or both.[3-6, 13] This complicates interpretation of results from in vivo models since additional treatment is needed to induce ovulation, most studies resorting to PMSG-hCG regimens. A second major problem is the lack of information on drug distribution in the human, including complete lack of data on genital tract tissue levels (for example, follicular fluid or ovarian, tubal, or uterine tissue). Half-life estimates (~5 days) from labeled tracer studies[14] have suggested that the clomiphene citrate should be present well after midcycle in the human, with 2- to 3-hour postdrug plasma levels in the range of 10^{-7} mol/L.[15] The possibility of accumulation or sequestration in tissues with high estrogen receptor levels also cannot be excluded.

Little is known about the fate of zuclomiphene and enclomiphene after oral administration. In a survey of five patients, plasma concentrations of each isomer were 9 to 80 ng/ml approximately 3 hours after a single 100 mg oral dose.[15] A preliminary report also suggests a differential elimination rate of the two clomiphene isomers such that plasma concentration of the zuclomiphene citrate was essentially identical for the 96-hour study period whether the oral dose contained 40% zuclomiphene (Clomid) or 55% zuclomiphene (Serophene).[16] Zuclomiphene citrate was also easily quantitated in plasma 28 days after a single 50 mg oral tablet. Since it appears that in the human, tissues have a prolonged exposure to clomiphene citrate and the currently used animal models do not respond by ovulation when treated with clomiphene citrate, we were interested in determining whether a more prolonged and extracorporeal exposure to clomiphene citrate and individually its isomers zuclomiphene and enclomiphene citrates would provide a clearer picture of any embryotoxic effects of the drug.

The results reported here suggest a significant effect of oocyte or embryo exposure to clomiphene citrate and its isomers as determined by fertilization rates, blastocyst formation, and degeneration rates. These effects are first apparent at concentrations of 5 to 10 μg/ml of either isomer in the culture media, which is close to the estimated plasma range. There does not appear to be a significant difference between either of the isomers or the racemic mixture in terms of the magnitude of the adverse effects. This would also suggest that the effects are not directly related to the estrogenic or antiestrogenic properties of the compounds. Supporting this conclusion are the results of the experiments demonstrating no protective effect of 17β-estradiol on the clomiphene citrate–induced decreases in embryo growth rates.

A second and important finding was the delayed effect of enclomiphene, zuclomiphene, or clomiphene citrate on embryo growth. As shown in Figs. 3 and 6, at lower concentrations there was a 24- to 48-hour interval between drug exposure and a decline in growth rate and an increase in degeneration rate for oocytes fertilized both in vitro and in vivo. This transition time is evidenced by the decreased rate of blastocyst formation at 10 μg/ml of enclomiphene or zuclomiphene but essentially no significant change in the degeneration rate. Growth has been significantly slowed and, with follow-up for longer periods of time, degenerative changes would undoubtedly appear. This obviously may also pertain to lower dosages of either clomiphene citrate or its isomers in that drug-induced alterations at drug concentrations of 0.1 or 1 μg/ml may have their effect at or beyond the blastocyst stage. These results differ critically from those reported by Laufer et al.,[12] who suggested that there are no changes in growth rate after the embryo reaches the two-cell stage. However, the oocytes used in that study were pretreated with clomiphene citrate for only 6 hours so that the oocyte was exposed for a short time to the drug. Second, the rate of fertilization was relatively low (<60%) in that study, making interpretation more difficult.

Exposure of the embryos to either clomiphene citrate or its isomers for 72 hours instead of 24 hours did not alter either the rate of blastocyst formation or the embryo degeneration rate for the 72- to 96-hour time period studied. Whether postblastocyst development would be affected is speculative at this time, but obviously embryo transfer of these exposed embryos to recipient pseudopregnant mice would help address that issue. It therefore appears that at least with early embryo-toxic events, the mouse embryo is sensitive to clomiphene citrate or its isomers through the two- to four-cell stage. The alterations in growth rate and degeneration also are not dependent on changes at fertilization, since exposure of the embryos fertilized in vivo to clomiphene citrate or its isomers yields results similar to those of the group fertilized in vitro. Late exposure of mouse embryos (≥eight cells) does not ap-

pear to slow embryo growth rate or increase degeneration rates until concentrations of 25 μg/ml or more of zuclomiphene or enclomiphene are used.

The present study clearly demonstrates a dose-dependent decrease in fertilization and embryo growth and an increase in embryo degeneration when either oocytes fertilized in vitro or two-cell embryos fertilized in vivo are exposed in vitro to zuclomiphene, enclomiphene, or the racemic mixture clomiphene citrate. These findings would correspond to those of earlier work with in vivo models. On the other hand, the evidence presented here clearly suggests that exposure to zuclomiphene, enclomiphene or, clomiphene citrate either during fertilization or through the two- to four-cell stage has potential long-term embryo-toxic effects, implying that even embryos demonstrating early progressive cleavage may later undergo diminished embryo development and have an increased degeneration rate. Subtle changes within the embryo may eventually lead to the embryo's death long after initial exposure to the drug.

The clinical implication of these data is that the embryo-toxic effects of clomiphene citrate may in part be responsible for the discrepancy between ovulation and pregnancy rates and the increased spontaneous abortion rate. While clomiphene citrate has enjoyed widespread use as an ovulatory agent, care must be taken to use the lowest effective dose to minimize exposure of the gametes and early embryos to the drug.

Discussion

Dr. Daniel R. Mishell, Jr., Los Angeles, California. Clomiphene citrate is widely used in in vitro fertilization programs to induce maturation of more than one follicle. In these programs it has been shown that the probability of effecting a successful pregnancy is directly correlated with the number of embryos transferred. Because earlier reports summarizing the experience of the use of clomiphene citrate to induce ovulation in anovulatory women have shown a discrepancy between presumptive ovulation rates and pregnancy rates, it has been postulated that clomiphene citrate may have a toxic effect on the developing embryo. Such an effect could also account for the low pregnancy rate after human embryo transfer. This study was undertaken in an attempt to determine if this agent did indeed have an adverse effect on fertilization and embryo growth using the mouse model. After completion of this study, it was concluded that both clomiphene citrate and each of its two isomers had an adverse effect on fertilization, blastocyst formation, and embryo development of the mouse because each of these parameters was altered adversely in a dose-dependent manner as the concentration of each of these three agents increased. Nevertheless, these data should not be used to indicate that these alterations in parameters of in vitro mouse fertilization and embryo growth rates are also responsible for the differences between ovulation and pregnancy rates reported in women treated with this drug to induce ovulation. The authors also state that there is an increased spontaneous abortion rate in human pregnancy after the use of clomiphene citrate, and the embryotoxic effect observed in this study may be the responsible factor. The data generated do not support such a conclusion for the following reasons.

First, adverse effects on fertilization, embryo development, and blastocyst formation were observed only with drug concentrations of ≥10 μg/ml when clomiphene or its isomers were added directly to the culture media in this in vitro system. Three hours after ingestion in the human, serum concentrations of clomiphene

citrate have been found to be in the 9 to 80 ng/ml range and thus the concentrations to which human gametes and embryos are exposed several days after ingestion of the last tablet are at most <1% of the minimally significant toxic dose observed in this mouse study.

Second, since no positive controls were used, it has not been proved that the adverse effects observed were due to the drug itself. They may have been due to alterations in metabolic parameters, such as osmolarity and pH, in the tissue culture system produced by this relatively high concentration of drug. Maintenance of constancy of these and other environmental parameters is extremely important to ensure optimal rates of fertilization and embryo development in any in vitro system. Dr. Kim, were these and other parameters measured in this study and, if so, did they remain constant after addition of different concentrations of the drug?

Third, it is important to know whether a sufficient number of repetitive trials with a sufficient number of embryos were performed to provide statistical validity. Variation in numbers of animals and gametes used as well as culture conditions can influence the outcome of in vitro fertilization. How many repetitive experiments were performed in each study group and what was the variability of results among the experiments?

Finally, the references used by the authors to demonstrate that ovulation induction with clomiphene citrate in the human is associated with a lower pregnancy rate than fertilization rate and a higher rate of spontaneous abortion were reports from the 1960s in which strict criteria for enrollment of subjects, dosage of drug, and duration of therapy were not used. The results are different in more recent studies in which enrollment criteria, dosage, and follow-up were better controlled and actuarial statistical techniques used. In a 10-year follow-up study of 428 women treated with an individualized variable treatment regimen, Gysler et al.[1] found that although the overall incidence of ovulation was 85.3% and that of pregnancy was 42.8%, the pregnancy rate was 88.2% among couples with no other infertility factor who ovulated with clomiphene citrate treatment.

Hammond et al.[2] recently reported similar results. During a 5-year study of 159 patients treated with clomiphene citrate, 86% ovulated and 49% conceived, but with the use of life-table analysis they found that the pregnancy rate over time after clomiphene citrate treatment, provided no other infertility factors were present, was nearly identical to that of normal fertile couples. In their study, if the women did not discontinue treatment, the cumulative conception rate after 10 cycles of clomiphene citrate treatment was more than 95%, similar to the rate of conception in this same time period among normal women discontinuing contraception to conceive. In these two studies the spontaneous abortion rate was 14% and 15%, respectively, similar to that observed in other studies of large numbers of previously infertile patients who conceived and similar to the incidence of clinically recognized spontaneous abortion in all human populations.

Thus these two reports do not indicate that the use of clomiphene citrate administered orally before ovulation has an adverse effect on fertilization or embryo development in the human.

The clinical implications of data obtained from animal studies using an in vitro system should not be overinterpreted. In disagreement with the conclusion of the essayist, the results of the study reported today showing adverse effects on fertilization and embryo development of high dosages of clomiphene citrate when added directly to a mouse in vitro system should not be extended to interpret effects of the clinical use of this highly effective ovulation-inducing agent.

DR. ROBERT B. JAFFE, San Francisco, California. In addition to the relatively high doses of clomiphene that were used in this study, the time of exposure in the in vivo experiments was far different from the time that we use clomiphene in inducing ovulation in women, and I wondered why that particular timing of administration was employed.

DR. GERE S. DIZEREGA, Los Angeles, California. A number of years ago a couple of reports demonstrated morphologic abnormalities in karyotypes of neonates from patients who had received clomiphene citrate for ovulation induction. Although these pregnancies resulted in clinically normal infants, some of the karyotypes contained morphologic abnormalities that were classified as "gene breakages." I wondered many times since then, Dr. Kim, if someone had a chance to perform a dose-response study as you did with clomiphene in sufficient doses to induce gross abnormalities that would be an opportunity to readdress those bothersome data.

Did you have a chance to do karyotyping of any of the embryos, and if so, were there any abnormalities?

DR. KIM (Closing). I agree with Dr. Mishell that any in vitro data should be applied to the in vivo situation with many considerations.

As to the question concerning the condition of the culture, our preliminary study had shown no change in the culture media when clomiphene citrate was added. Therefore we did not check the osmolarities or other elements in each experiment. However, pH was measured every day, and there was no gross change in the pH.

In terms of variability of the experiments, we performed one series of experiments including the control and study groups in 1 day to eliminate the variability of the experimental conditions. The results were pooled for the statistical analysis. The critical question

was raised concerning the concentrations of the drug used in the study, whether it is a physiologically acceptable range or not. Unfortunately, there are no data available regarding follicular or plasma concentration of clomiphene citrate in humans or animals since assay technique was such that one could not measure accurately. However, there have been some metabolic studies of clomiphene citrate from which we can learn.

Harmon and Blackman (see reference 15) published the high–performance liquid chromatography method of measuring clomiphene citrate, which is what Dr. Mishell quoted. In that study a single dose of 100 mg administered orally would give approximately a 30 to 80 ng/ml concentration, and concentrations of the isomers are variable because metabolic clearance rates of these two isomers are quite different. Mikkelson et al. (see reference 16) also showed that after a single dose of 50 mg of clomiphene citrate was given to a healthy woman, zuclomiphene, for example, was detectable in plasma as long as 14 days later. Other investigators have demonstrated that 50% of carbon 14–labeled clomiphene citrate was excreted in 5 days. Considering the half-life of 5 days and the concentration from a single 100 mg dose and pharmacologic cumulative effects of the drugs, when more than a 150 mg daily dosage is given for 5 days, plasma concentration will be somewhere between 1 and 10 μg/ml. This was only a theoretical estimation. For that reason we decided to study the range of 0.1, 10, and 25 μg/ml.

The question raised by Dr. Jaffe regarding a high dosage of clomiphene is important. Certainly 25 μg/ml of clomiphene citrate is not a physiologic but a pharmacologic level. The idea of the project was to show if there was a dose-dependent factor in terms of its effect on the embryos. Therefore a high dose range was tested.

Finally, Dr. diZerega brought up an important question regarding genetic aspects of the embryos exposed to clomiphene citrate. We have not done such a study. Karyotyping would be the important next step to investigate the cytotoxicity of this drug.

Use of two different deoxyribonucleic acid probes to detect Y chromosome deoxyribonucleic acid in subjects with normal and altered Y chromosomes

Paul G. McDonough, M.D., Sandra P. Tho, M.D., John J. Trill, M.S., J. Rogers Byrd, Ph.D., Richard H. Reindollar, M.D., and Jay A. Tischfield, Ph.D.
Augusta, Georgia

Four experiments evaluated the sensitivity and specificity of molecular techniques to detect human Y chromosome deoxyribonucleic acid. In experiment I, electrophoretic separation of normal male deoxyribonucleic acid fragments after digestion with endonuclease *Hae* III revealed two male-specific bands of 3.4 and 2.1 kilobase (kb). These bands were not visible if the fraction of male deoxyribonucleic acid in mixed samples was less than 0.3. In experiment II, by means of a repetitive copy Y deoxyribonucleic acid probe (pS4) mapped to Yq12, a male-specific 2.3 kb band was detectable in mixtures of 2.5 ng of male deoxyribonucleic acid and 997.5 ng of 45,X female deoxyribonucleic acid. In experiment III, hybridization with the pS4 probe was performed on the deoxyribonucleic acid of 20 subjects with a normal or a variant Y chromosome. In experiment IV, deoxyribonucleic acid from the same subjects was hybridized to a single copy probe (4B-2) mapped to the Yq11 region. Deoxyribonucleic acid from category A subjects (n = 8) with cytologically normal Y chromosomes hybridized to both deoxyribonucleic acid probes. Deoxyribonucleic acid from category B subjects (n = 2), including a variant Y chromosome that was negative for Q-banding but positive for C-bands, hybridized with the distal pS4 and proximal 4B-2 probes. Deoxyribonucleic acid from category C subjects (n = 10) with variant Y chromosomes uniformly negative for Q- and C-bands, did not hybridize with the pS4 probe. Deoxyribonucleic acid from three of the 10 category C subjects did hybridize to the more proximal sequence–detecting 4B-2 probe. Deoxyribonucleic acid from the remaining seven subjects in category C did not hybridize with either of the deoxyribonucleic acid probes. (Am J Obstet Gynecol 1986;154:737-48.)

Key words: Normal/variant Y chromosomes, deoxyribonucleic acid (DNA) probes, pS4, 4B-2

Detection of a minority population of cells with a Y chromosome in a putative mosaic 45,X individual, or clarification of a chromosomal fragment suspected to be Y, by cytogenetic techniques is difficult and frequently uninformative. The clinician can sometimes resolve the dilemma only by prophylactic extirpation of the dysgenetic gonads in individuals at risk for having an undetected Y chromosome in a small fraction of cells. Cytogenetic techniques to identify and study the Y chromosome can now be complemented by the use of Y-specific deoxyribonucleic acid (DNA) probes.

Cooke and associates were the first to recognize that DNA from males which is digested with the restriction enzyme *Hae* III yields two male-specific fragments with molecular sizes of 2.24×10^6 (3.4 kilobase pairs) and 1.6×10^6 (2.1 kb pairs), respectively. These two fragments are composed of moderately repetitive DNA sequences that are visible on agarose gels stained with ethidium bromide and viewed under short-wave ultraviolet light (250 nm).[1] The 3.4 kb (DYZ1*) fragment class has been mapped to Yq11-q12. This region includes the heterochromatic and euchromatic portion of the long arm of the human Y chromosome. The 2.1 kb (DYZ2*) fragment class has been mapped exclusively to the heterochromatic region of the Y chromosome Yq12 → qter.[2,3] These reiterated male-specific sequences (3.4 kb, 2.1 kb) constitute approximately 40% and 20%, respectively, of the DNA of the human Y chromosome.[4,5]

Recently Disteche et al.[6] constructed a Y-specific DNA probe from a 850 base pair (bp) nucleotide sequence derived from the 2.1 kb *Hae* III repetitive DNA fragment visible on ethidium bromide–stained gels. After digestion of DNA with *Mbo* I, hybridizing Southern

*Category A subjects (1 through 8) had cytologically normal Y chromosomes and hybridized with both pS4 and 4B-2 probes. Category B (subjects 9 and 10) consisted of one subject with loss of Q-banding but intact C-bands and one subject with a dicentric Y chromosome in multiple cell lines. Subject 9, positive for C-heterochromatin, still hybridized with both probes. Category C subjects with del(Y)(q12) fell into two categories depending on whether they hybridized with the proximal 4B-2 probe. Subjects in the C_1 category (subjects 11-13) hybridized with the 4B-2 sequences, whereas the remaining subjects (14-20) did not demonstrate a 4B-2 band.

†Dysgenetic tumors: dysgerminoma (No. 1), gonadoblastoma (No. 17), and embryonal carcinoma (No. 19).

blots to this repetitive Y probe (pS4) allows one to discern a clear distinction between male and female DNA, with male DNA exhibiting a sex-specific 2.3 kb band of hybridization. Recent evidence suggests that the upper limits of the pS4 sequences on the Y long arm are defined by the upper limits of C-banding and hence are contained within Yq12.[7]

Burke et al.[8] isolated a single copy DNA probe, 4B-2, which maps to the proximal portion of the long arm of the human Y chromosome (subcentromeric → q11), placing it entirely in the euchromatic region.

DNA-based techniques to identify Y chromosome DNA in putative mosaic 45,X/46XY subjects or to confirm the presence of a suspected Y fragment may assist in identifying subjects at risk for dysgenetic tumors. The utility of molecular probes for Y in this clinical situation will depend upon their potential to detect (1) small amounts of Y chromosome DNA in mosaic 45,X/46,XY subjects and (2) structurally altered Y chromosomes, especially del(Y)(q12). Four different but related experiments using a combination of Y DNA probes were designed to evaluate the extent to which these two variables involving sensitivity and specificity may affect the molecular identification of human Y DNA in mosaic 45,X/46,XY subjects.

Material and methods

General procedures

Plasmid isolation. The DNA probe pS4 (supplied by D. Hoar), which hybridizes to repetitive sequences on the Y chromosome, consists of a 850 bp *Pst* I nucleotide

sequence derived from the 2.1 kb *Hae* III DNA fragment regionalized to the heterochromatic region of the long arm of the Y chromosome.[6] The probe 4B-2(supplied by K. Smith) is a recombinant phage construct containing a single copy 3.3 kb *Eco* RI fragment which maps to the proximal portion of the euchromatic region of the long arm of the Y chromosome. The recombinant plasmid was constructed from *Eco* RI digestion of the recombinant phage 4B-2 and insertion of the gel-purified fragment into the *Eco* RI site of pBR 322.[8] Both plasmids were propagated in *Escherichia coli* HB101. The bacteria were grown in Luria broth containing ampicillin. The plasmids were amplified with use of chloramphenicol and isolated according to the method of Ish-Horowitz et al.[9] The plasmids were digested with restriction enzymes, and the resulting fragments were purified through elecrophoresis on 0.8% low melting point agarose gel followed by purification with a NACS prepak column (Bethesda Research Laboratory) according to the manufacturer's recommendations.

DNA isolation. Total genomic DNA was isolated from 20 to 30 ml of ethylenediaminetetraaccetae–whole blood. The blood was mixed 1:1 with lysis buffer (1 mmol/L of magnesium chloride, 1 mmol/L of sodium phosphate (monobasic), ph 6.5, 0.8% Nonidet-P40, and 0.4% deoxycholate) and centrifuged in a JA20 rotor at 10,000 rpm for 30 minutes at 4° C. The pellet containing nuclei was dissolved in 10 ml of TEN (10 mmol/L of Tris, pH 8.3, 150 mmol/L of sodium chloride, and 5 mmol/L ethylenediaminetetraacetate), 3.5 ml of 5 mol/L sodium perchlorate, and 1.5 ml of 10% sodium dodecyl sulfate and digested for 1 hour at 65° C with proteinase K. The DNA was extracted twice with chloroform–isoamyl alcohol (24:1) and precipitated through the addition of ½ vol of 7.5 mol/L of ammonium acetate and 2 vol of absolute alcohol. The DNA was lypholyzed and subsequently dissolved in 1X TE plus 1X SSC (sodium citrate/sodium chloride), digested with pancreatic ribonuclease at 37° C for 30 minutes and redigested at 65° C for 1 hour with proteinase K. The DNA was then reextracted with chloroform-isoamyl alcohol and ethanol precipitated.

Restriction enzyme digestion, gel electrophoresis, and hy-

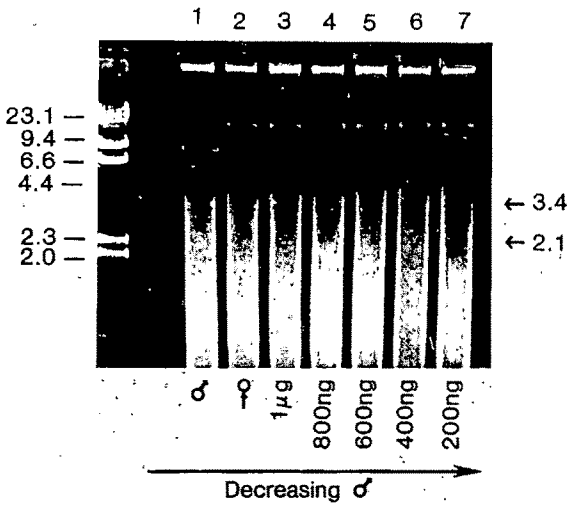

Fig. 1. *Hae* III restriction enzyme digests of normal male and female DNA, followed left to right by decreasing amounts of normal male DNA mixed with normal female DNA so that each lane has a total of 2 μg of the mixture. The 3.4 and 2.1 kb *Hae* III fragments are detectable down to 600 ng male to 1400 ng female DNA (30%) *(lane 5)*.

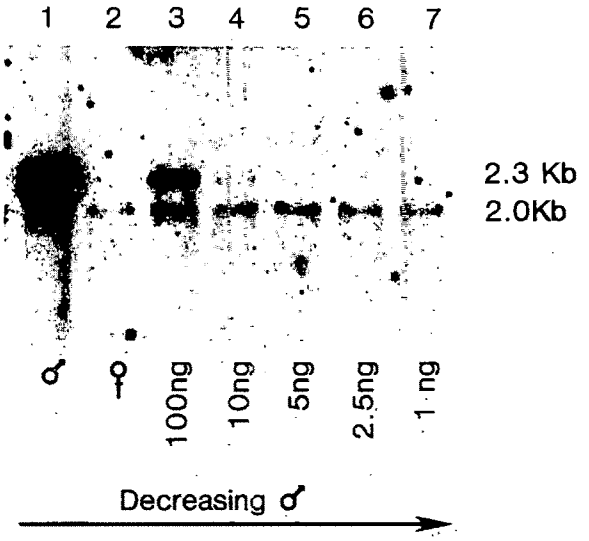

Fig. 2. A dilutional gel of *Mbo* I–digested DNA probed with pS4. *Lanes 1* and *2* represent normal male and 45,X female control samples. *Lane 3* represents a 1 μg mixture of 900 ng of 45,X DNA and 100 ng of normal male DNA. *Lanes 4* to 7 represent decreasing amounts of male DNA mixed with proportionately increasing amounts of 45,X DNA with maintenance of 1 μg of total DNA in each lane. The Y-specific 2.3 kb band is evident at the 5 ng concentration of male DNA, and possibly also at the 2.5 ng level. The 2.5 ng level represents a mixture of 2.5 ng/997.5 ng or 1 part male to 400 parts 45,X DNA.

bridization. Genomic DNA was digested with either *Hae* III, *Mbo* I, *Eco* RI, or *Hind* III under the conditions recommended by the supplier (BRL). The DNA was electrophoresed on 0.8% agarose gels and blotted with use of the method of Southern[10] to Gene Screen Plus filters (New England Nuclear). The filters were hybridized to either the pS4 or 4B-2 probes, which were phosphate 32 labeled by nick translation[11] and washed as recommended by the supplier. After the final wash the filters were washed for an additional 90 minutes at 65° C in 0.1X SSC with 1% sodium dodecyl sulfate.

Specific experiments

Experiment I: dilutional gel of male and female DNA digested with Hae *III.* Progressively smaller amounts of normal male DNA (2 μg to 200 ng) and normal female DNA were mixed to yield a final concentration of 2 μg. The mixtures were digested with *Hae* III and electrophoresed (2 μg/well) on a 0.8 agarose gel. After staining with ethidium bromide the gels were photographed on Kodak Technical Pan Film through orange, yellow, and ultraviolet contrast filters, under illumination with a short-wave length ultraviolet light (250 nm).

Experiment II: dilutional gel of male and female 45,X DNA digested with Hae *III or* Mbo *I and hybridized with pS4 plasmid.* Decreasing amounts of normal male DNA (100 ng to 10 pg) were mixed with female DNA from a 45,X gonadal dysgenesis subject, to a final concentration of 1 μg per lane, and digested separately with either *Hae* III or *Mbo* I. 1 μg each of the digested DNA dilutions was electrophoresed on a 0.8 agarose gel, blotted, and hybridized to a ^{32}P–labeled 850 bp *Pst* I fragment isolated from pS4.

Experiment III: Mbo *I digestion and hybridization with pS4 probe of DNA of study subjects.* The third experiment was designed to compare the specificity of molecular and cytogenetic techniques in the assessment of normal and altered Y chromosomes. Genomic DNA from all subjects (n = 20) and their fathers (n = 14) was digested with *Mbo* I, and 1.5 μg of DNA per well was electrophoresed on a 0.8% agarose gel, blotted, and hybridized to the pS4 probe as above.

CLINICAL SUBJECTS. All study subjects (n = 20), except one, were 45,X/46,XY mosaics with normal Y (n = 8) or variant Y (n = 12) chromosomes (Table I). In one of the 12 subjects with a variant Y chromosome a 45,X cell line was not detected (subject 9). The single cell line from this subject with an altered Y chromosome was obtained from amniotic fluid culture (maternal age indicated) at 16 weeks of gestation. The product of this pregnancy, now 3 months of age, is a normal-appearing male infant with bilateral scrotal testes. All other karyotypes (n = 19) were done on cells from peripheral blood.

The clinical phenotypes of the 20 subjects with normal and variant Y chromosomes ranged from phenotypic men with bilateral scrotal testes (n = 3) to women with Turner or quasi-Turner phenotypes (n = 17). The 17 phenotypic women had bilateral streak gonads (n = 12) or a unilateral streak gonad with a contralat-

eral testis (n = 5). Dysgenetic tumors occurred in three of the subjects. Two of the 17 phenotypic women had one or both rudimentary gonads replaced by a tumor. One patient (age 20 years) had a unilateral gonadoblastoma (subject 17) and the other at 15 years of age had bilateral tumors, dysgerinoma, and gonadoblastoma (subject 1). One enigmatic subject (No. 19) with a left intra-abdominal testis and right contralateral streak that were both extirpated at 5 years of age developed a tumor in a second right inguinal testis at the age of 15 years. The clinical and cytogenetic data are tabulated in Table I.

Cytogenetic analysis. Before DNA analysis all subjects were rekaryotyped in peripheral blood to update the percentage of mosaicism, to reclarify the structure of variant Y chromosomes, and to ensure that the molecular analysis was performed on the same sample from which the current percentage of mosaicism had been determined. The father of each proband, when available (n = 14), was karyotyped for comparison of Y structure. A minimum of 50 cells was counted, and five cells were karyotyped in all study samples. G-, Q-, and C-banding were performed on every study sample before DNA analysis on the same sample.

Based on the cytogenetic findings, the study subjects at this time were placed into three categories. Category A subjects had normal Y chromosomes by all cytologic parameters. Of category B subjects, one had a dicentric Yq and the other had a deleted Yq that eliminated Q-banding but preserved C-bands. Category C subjects were cytogenetically uniform in that they all appeared to have deletions of Yq that eliminated both Q- and C-bands (Table I).

Experiment IV: Eco *RI and*Hind *III digestion and hybridization with 4B-2 probe of DNA of study subjects.* To further categorize the deleted Y chromosomes (negative Q, negative C) in category C subjects, a fourth experiment was performed. Using normal men, women, and category A subjects as controls, all individuals in category C (n = 10) were further analyzed with the single copy DNA probe 4B-2. This probe, provisionally localized to the paracentric region of Yq, is proximal to the pS4 sequences.[8]

DNA from category A and C subjects was digested with either *Eco* RI or *Hind* III. The DNA was electrophoresed (7.5 μg per well) on 0.8% agarose gels, blotted, and hybridized to a ^{32}P-labeled 3.3 kb *Eco* RI insert isolated from the recombinant phage 4B-2 and subcloned into the *Eco* RI site of pBR 322.[8]

Results

Experiment I: dilutional gel of male and female DNA digested with *Hae* III. DNA from normal men cut with the restriction enzyme *Hae* III yielded two male-specific fragments. These fragments were 3.4 and 2.1 kb in size, and were not visible in *Hae* III–digested DNA from normal female controls (Fig. 1, lanes 1, 2).

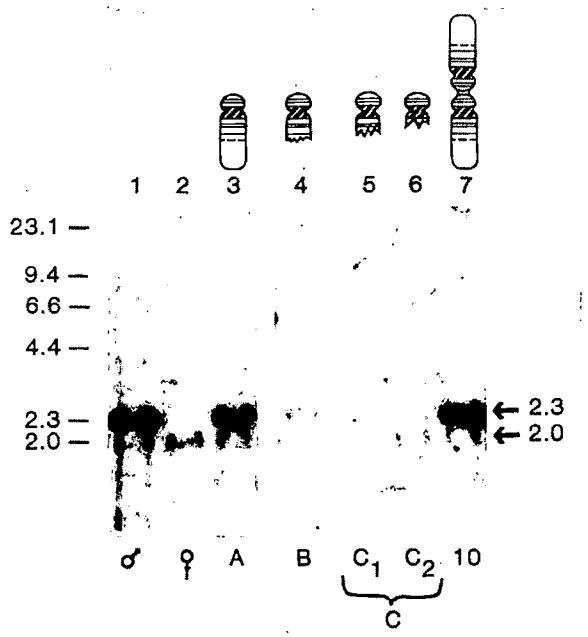

Fig. 3. An autoradiogram of total genomic DNA digested with *Mbo* I and probed with pS4. The lanes from left to right are as follows: *lane 1,* 1.5 μg of control normal male DNA; *lane 2,* 1.5 μg of control normal female DNA; *lane 3,* 1.5 μg of DNA from case 1, representative of cases 1 to 8 in the normal Y category (category A); *lane 4,* 600 ng (0.6 μg) of DNA from case 9, deleted of Q-bands but still positive for C-banding (category B); *lanes 5 and 6,* 1.5 μg of DNA from cases 11 and 19, representative of study subjects deleted of Q- and C-bands (category C); *lane 7,* 1.5 μg of DNA from subject with dicentric Y long arm.

In mixtures containing equal amounts of male and female DNA (1 μg/1 μg, lane 3) both of these bands were clearly visible on agarose gels. When female DNA was mixed with decreasing amounts of male DNA and electrophoresed on a gel, the bands were visible in photographs down to a concentration of 600 ng (30%) of total male DNA. With amounts of normal male DNA, less than 600 ng, these bands were not easily discernible (Fig. 1, lanes 3 through 7).

Experiment II: dilutional gel of male and female 45,X DNA digested with *Hae* III, *Mbo* I, and hybridized with pS4 plasmid. Normal male and female DNA restricted with *Hae* III and probed with pS4 exhibited a 2.1 kb band of hybridization. This single band, though less intense in female DNA, was present in both sexes. In DNA from controls and study subjects a distinct male-specific band was not evident with the *Hae* III digest and pS4 probe.

Normal male and 45,X female DNA restricted with *Mbo* I and probed with pS4 showed clear differences.[12] Male DNA, exhibiting tenfold more hybridization than female DNA demonstrated a 2.3 kb male-specific band.

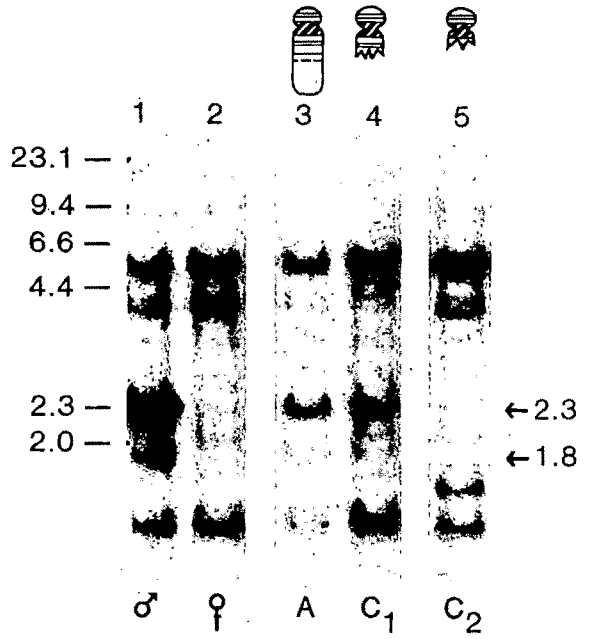

Fig. 4. Autoradiograms of total genomic DNA digested with *Hind* III followed by hybridization with 4B-2. *Lanes 1* and *2* represent normal male and normal female DNA. Normal male DNA after *Hind* III restriction has 2.3 and 1.8 kb fragments not present in female DNA. *Lane 3* represents one subject from category A with a morphologically normal Y chromosome. *Lane 4* is representative of subjects 11, 12, and 13 from category C deleted of Q- and C-bands, who hybridize with the 4B-2 probe and demonstrate the two male-specific fragments (category C_1). *Lane 5* is representative of the remaining seven subjects (14 to 20) in category C who do not hybridize with the 4B-2 probe (category C_2).

In gels containing 900 ng of 45,X DNA and 100 ng of male DNA this Y-specific 2.3 kb band was easily detected. This was visible down to an amount of 2.5 ng of male DNA. This represents a detection of 1 part male DNA in 400 parts 45,X DNA (Fig. 2).

Experiment III: *Mbo* I digestion and hybridization with pS4 probe of DNA of study subjects

Clinical subjects and cytogenetic analysis. The clinical and cytogenetic data in the 20 study subjects are tabulated in Table I.

CATEGORY A (N = 8). Subjects 1 thru 8, assigned to category A, and their fathers had morphologically normal Y chromosomes that were positive for Q-, G-, and C-bands. The percentage of 46,XY cells in peripheral blood ranged from a low of 10% (subject 1) to 94% (subject 8). Included in this category was one subject with bilateral dysgenetic tumors (No. 1), one subject with bilateral scrotal testes (No. 7), and two with unilateral testis and contralateral streak gonad (subjects 6 and 8).

CATEGORY B (N = 2). One subject (No. 9) was placed in this category because of his cytogenetic uniqueness. The morphology of the Y chromosome was intermediary between the normal Y (category A), and the morphologic variants seen in category C. The subject was a normal male phenotype initially ascertained in amniocyte culture, in whom a 45,X cell line had not been detected. The Y chromosome in the single cell line was completely negative for distal long arm Q-banding, but a distinct terminal heterochromatic band was evident with C-banding.

The second subject in category B (No. 10) had a dicentric Y chromosome, with loss of Yp and duplication of Yq, and was the only subject who was theoretically disomic for DNA on the long arm of the Y chromosome.

The fathers of both subjects (Nos. 9 and 10) in category B had cytologically normal Y chromosomes with distinct Q- and C-bands.

CATEGORY C (N = 10). Category C consisted of 10 subjects with clear morphologic deletions in their Y chromosome. All subjects in category C were negative for Q- and C-bands. The size of the Y was reduced in all subjects and in four subjects was simply a small minute centric fragment, acentric fragment, or ring (subjects 13, 14, 16 and 17). No further attempts with use of cytogenetic techniques were made to resolve the precise nature of these deleted chromosomes. The percentage of the variant Y cell line in category C subjects ranged from 14% (No. 11) to 92% (No. 13). The studied paternal Y chromosomes in category C were morphologically normal and positive for Q- and C-bands.

In this category were two subjects with tumors (Nos. 17 and 19), one azoospermic male with testicular failure and small bilateral scrotal testes (No. 20), and two subjects with unilateral testis and contralateral streak gonad (Nos. 15 and 19).

DNA analysis (Mbo *I, pS4).* The presence or absence of the 2.3 kb male-specific band is indicated for each individual subject in Table I. The autoradiographs, representative of each of the three cytogenetic categories, are seen in Fig. 3.

All subjects in category A with morphologically normal Y chromosomes had a distinct 2.3 kb band. This band was present in every category A subject (Nos. 1 to 8), even at the lowest level of XY mosaicism (10%) (Fig. 3, lane 3).

The subject in category B who was negative for Q-bands but positive for C-bands (No. 9) had the 2.3 kb male-specific band but at a reduced intensity (Fig. 3, lane 4). The subject with dicentric Yq (No. 10) exhibited the 2.3 kb band in increased intensity compared to a normal male control (Fig. 3, lane 7).

No subject in category C (Nos. 11 to 20) devoid of Q- and C-bands demonstrated the 2.3 kb band (Fig. 3, lanes 5, 6).

Experiment IV: *Eco* RI and *Hind* III digestion

and hybridization with 4B-2 probe of DNA of study subjects

DNA analysis. Digestion of normal male DNA with *Hind* III and blot hybridization with 4B-2 yields hybridization bands of 2.3 and 1.8 kb. These bands are not seen in autoradiograms of digested and blotted female DNA (Fig. 4).

Digestion of genomic DNA with *Eco* RI, and blot hybridization with the 4B-2 probe yields a single male-specific hybridization band of 3.3 kb. Normal female DNA does not demonstrate this band (Fig. 5).

The results of the 4B-2 probing after the *Hind* III and *Eco* RI restriction are tabulated for individual subjects in Table I and representative autoradiograms presented in Figs. 4 and 5.

Normal males and all category A subjects demonstrated the male-specific 2.3 kb, 1.8 kb *Hind* III, and 3.3 kb *Eco* RI fragments. Three of the 10 category C subjects (Nos. 11, 12 and 13) whose DNA failed to hybridize with the pS4 probe, hybridized with the 4B-2 single copy probe after both *Hind* III and *Eco* RI restriction. Representative autoradiograms from this group, referred to as category C_1, are depicted in Figs. 4 and 5 (lane 4). The remaining seven subjects in category C (Nos. 14 to 20) had DNA which failed to hybridize with the 4B-2 probe and were hence assigned to category C_2 (Figs. 4 and 5, lane 5).

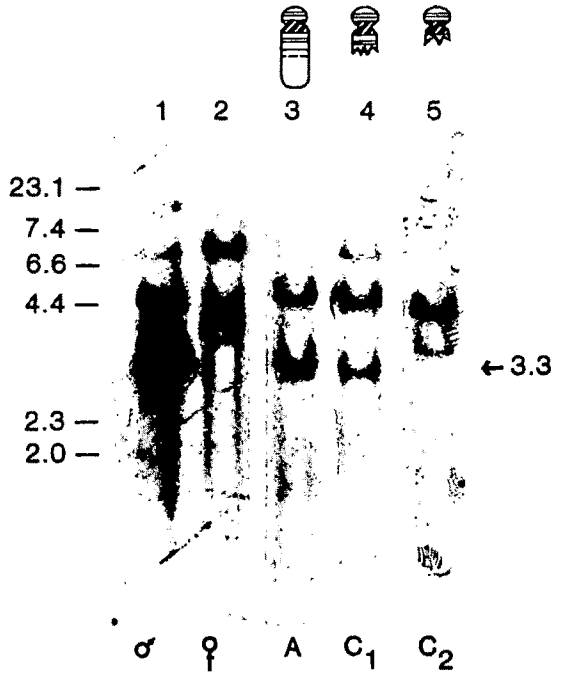

Fig. 5. Autoradiograms of total genomic DNA digested with *Eco* RI followed by hybridization with 4B-2. Male DNA *(lane 1)* has a 3.3 kb band not present in female DNA *(lane 2)*. Category A and C_1 subjects demonstrate this band *(lanes 3 and 4)*, but it is not seen in category C_2 subjects *(lane 5)*.

Comment

This series of four experiments addresses the ability of specific molecular techniques to identify human Y chromosome DNA. The clinical usefulness of these techniques will depend on their sensitivity and precision. The technique used in experiment I is quite practical but limited in sensitivity and precision. DNA extraction, digestion (*Hae* III), electrophoresis, viewing under ultraviolet light, and final analysis take approximately 2 days. By eliminating blotting and hybridization with a Y-specific probe, one shortens the time required for analysis but decreases sensitivity. This technique was not able to detect Y chromosome DNA in dilutional mixtures containing less than 30% normal male DNA. Conventional cytogenetic techniques, though more time consuming, have greater sensitivity. The precision of this technique (experiment I) is limited somewhat by the regional localization of the 3.4 and 2.1 kb repetitive fragments. These bands represent moderately repetitive DNA sequences interspersed throughout the long arm of the Y chromosome but located principally in the heterochromatic area. A deletion of Y (q12) eliminates the majority of these sequences and further restricts the precision and sensitivity of this technique. This abbreviated technique is nevertheless quite adequate for routine molecular sexing when nonmosaic 46,XY cell lines and morphologically normal Y chromosomes are the rule, rather than the exception.

Experiment II demonstrates that these problems of sensitivity and precision can be resolved in part by the use of Y-specific DNA probes. The male-specific repetitive DNA probe pS4, in mixtures of 45,X and 46,XY DNA, was able to detect down to 2.5 ng of male DNA. This probe detected male-specific DNA sequences except for the subjects with Yq deletions, which involved loss of both Q- and C-bands. The DNA from the 10 individuals with Y chromosome deletions proximal to the termination of C-banding (category C) did not hybridize with the pS4 probe. The one subject (No. 9) with a Yq deletion who demonstrated a distinct 2.3 kb Y-specific band still had a small distinct C-band on the Y long arm (category B). The *Mbo* I, pS4 2.3 kb band in this subject, devoid of Q-bands but positive for C-banding, suggests that the sequences corresponding to the pS4 probe are defined on Yq by the upper limits of C-banding and are not restricted to the Q positive region. The molecular data, contrary to general cytogenetic opinion, suggest that the chromosomal regions representing the C- and Q-bands do not overlap in their entirety. C-heterochromatin, as defined by the upper limits of the pS4 sequences, seems to extend more proximal than Q-banding.

Experiment III clearly defines the limits of the pS4

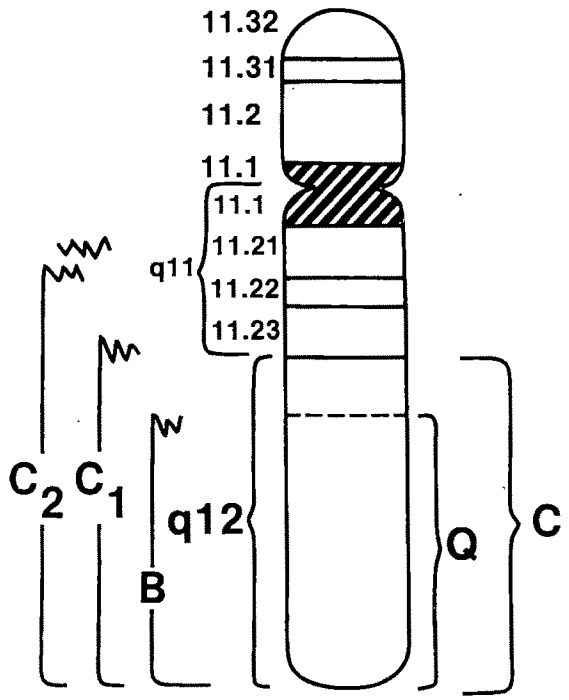

Fig. 6. A schematic representation of the extent of the deleted Yq in each of the three categories of Y variants is compared to the normal category A. In variant B the breakpoint extends to the top of the Q-band but does not reach to the top of the C-band. Type B variant, similar to a cytogenetically normal Y (category A), hybridizes with both the pS4 and the 4B-2 probes. Type C_1 variant is indistinguishable from type C_2 variant cytogenetically. Both variants are devoid of Q- and C-bands. Type C_1 does not hybridize with pS4 but does hybridize with 4B-2, indicating a more extensive deletion than variant type B. Variant type C_2 does not hybridize with either probe and is presumed to have the most extensive deletion into the proximal portion of the long arm of Y, or alternatively to be isochromosomes for Yp with complete absence of long arm DNA.

sequences in this study group. A 2.3 Kb male-specific band is not seen in any of the 10 subjects with Yq deletions who have lost both C- and Q-bands (category C). One may assume that these 10 individuals have a Y deletion extending up into the euchromatic portion of the long arm of Y.

In experiment IV it is apparent that even the 10 individuals in category C who appear to be cytogenetically indistinguishable are not homogeneous on DNA analysis. The DNA from three of these subjects, when restricted with *Eco* RI and *Hind* III, hybridize with the more proximally located single copy 4B-2 (category C_1). The DNA of the remaining seven subjects, with presumably more extensive Y chromosome deletions, did not demonstrate the male-specific bands with this single copy probe (category C_2). This sugggests that the largest DNA deletions are present in these seven individuals. who are more or less cytogenetically indistinct from the other three del(Y) subjects (Fig. 6). Alternatively some of these seven subjects may have complete absence of Yq DNA. The severe variant chromosomes in these subjects may be isochromosomes for Yp or even represent fragments of X.

It is apparent from these four experiments that cytogenetic techniques will continue to be necessary to define the gross morphologic structure of variant Y chromosomes. DNA techniques can then be selectively used to more precisely characterize the limits of these alterations (Fig. 6).

Characterizing the DNA composition of the variant or altered Y chromosome may provide insight into the critical determinants for oncogenesis and gonadal differentiation. Sensitive and precise techniques to detect covert Y chromosome DNA, which are capable of identifying variant Y chromosome DNA, will help to define the population of individuals at risk for dysgenetic tumors and may provide clinical insight into their variant gonadal development. The widespread application of DNA technology to detect all variant Y chromosomes will require centromeric-specific Y probes.[13]

We gratefully acknowledge Kirby Smith and David Hoar for providing the pS4 and 4B-2 DNA probes. We thank David Muram, Sid Wilroy, and John Phillips for providing blood samples. This work constitutes publication 10 of the Human Genetics Institute, Medical College of Georgia.

Discussion

Dr. Gloria E. Sarto, Milwaukee, Wisconsin. From the time of the first descriptions of the human sex chromosomes, efforts to ellucidate the mechanism of sex determination have been directed toward the cytogenetic/phenotypic investigations of individuals with aberrant sexual differentiation. From these studies and others it is clear that genes in several parts of the genome are involved in the developmental process of both male and female sexual development. Though not the focus of this research, the study of structurally abnormal sex chromosomes indicates that specific genetic information on the Y chromosome is responsible for maleness and genetic information on the X chromosome is necessary for normal ovarian function.

The Y chromosome is one of the smallest human chromosomes; it comprises 0.5 to 1.0% of the total diploid amount of genetic material. Cytogenetic staining techniques indicate that a large portion of the Y chromosome is heterochromatic. Also, the Y chromosome is practically devoid of functional genes except those dealing with male sex determination—located on the short arm of the Y (Y_p)—and possibly those factors controlling spermatogenesis, located on the nonfluorescent part of the long arm of Y (distal Yq11).[1] Fifty percent of the Y is composed of repeated DNA sequences; however, efforts are being directed toward characterizing the human Y chromosome with respect to its single copy DNA content and function, which is the focus of this research.

Initially, before banding techniques, only large structural chromosome abnormalities could be discerned. With conventional banding and later with high resolution banding, the ability to pick up more subtle anomalies improved; however, the introduction of recombinant DNA technology to the field of genetics has proved to be an even more valuable tool. The haploid DNA content of the human genome is 3×10^9 bp. With around 400 bands detectable in the haploid complement, one can calculate that one band spans about 10^7 bp or about 10,000 kb. The techniques outlined and used by the authors allow them to identify target DNA fragments down to 2.3 to 3.3 kb, obviously a far greater resolution.

The purpose of the proposed study was to determine the sensitivity and the specificity of two DNA probes, pS4 and 4B-2, in individuals with normal and structurally abnormal Y chromosomes. The authors showed that the technique is useful in detecting small amounts of DNA. They proved that the DNA probes used are specific for Y chromosomes, that is, they are not detected in normal females and in fact are specific for the long arm of the Y (Yq). The 4B-2 sequence has been localized by Burk et al.[2] to be between Yq11 and Y chromosome subcentromeric region. The authors placed the sequence on the euchromatic region of the long arm of Y (Yq11), which may be a bit more distal than the localization stated by Burk et al. This is possible as the Yq11 band is quite broad. The authors state that of 10 individuals negative for both the distal long arm Q- and C-bands, three (category C_1) hybridized to the 4B-2 probe and seven (category C_2) did not. Recognizing the fact that even with prophase banding there are not a great number of bands on the euchromatic portion of the long arm of the Y chromosome, I would still like to ask if the authors attempted at all to use prophase banding on the cases in category C, to more clearly delineate where the break on the Y chromosomes occurred and consequently define more precisely where the 4B-2 sequence is localized.

Given the sensitivity of DNA probes, I would like to ask the authors what use this method would have in prenatal fetal sexing. Do they think it may be possible to use this technique to detect male fetuses, possibly from fetal cells circulating in the maternal peripheral circulation. Also, I would like them to comment on the possible uses of these DNA probes for localizing other factors on the Y such as those controlling spermatogenesis, presumably in Yq11, or perhaps the tendency for tumor development in 45,X/46,XY mosaics to particular portions of the chromosome.

In summary, the authors have shown, as have others, the usefulness of recombinant DNA techniques in clinical medicine. Specific DNA probes can be used to identify fragments of the Y not identifiable by cytogenetic methods. With the development of more probes localized to various positions along the Y chromosome, discrimination between other deletions like those noted in categories C_2 and C_1 will be possible. More important perhaps, particularly with respect to the Y chromosome, will be the ability to delineate the exact position of the male sex-determining genes on the short arm.

Dr. S. Elias, Chicago, Illinois. I would also like to compliment Dr. McDonough and his colleagues on a

most interesting and informative piece of work. I have two questions for Dr. McDonough.

You indicated that Y-specific probes could prove useful in providing some insight into the predisposition of neoplasia in individuals with gonadal dysgenesis and a Y chromosome. Two groups of patients known to be at increased risk are phenotypic females with X-linked recessive 46,XY gonadal dysgenesis as well as sex-reserved males with nonmosaic 46,XX complements. Have you had the opportunity to use your two DNA probes to study such individuals?

Second, although it appears to be a very complex story now, HY antigen is still considered to be somehow associated with testicular determinant(s). In your study group, have you tried to correlate the results from either of the Y-specific probes with the presence or the absence of HY antigen? This would be of particular interest in the subgroup with the Y structural abnormalities.

Dr. Paul G. McDonough (closing). I will respond to Dr. Sarto's comments and questions and also to Dr. Elias' questions.

First, I would like to discuss the possible resolution between cytogenetics and molecular genetics. Imaging the gap between cytogenetics and molecular genetics is not easy. Resolution differences between the two are measured in millions of base pairs compared to a single base pair change. A specific single copy gene may be 800 to 1200 bp, whereas an undefined cloned DNA segment may be 10 to 20 db, or 20,000 bp. An average chromosome like the X has 1×10^8 bp. The banding patterns on X give markers that are about 5×10^6 bp apart. In situ hybridization technology is capable of identifying gene sites in bands and subbands of stained prometaphase chromosomes. However, the level of resolution even with this technique within a subband may span 5×10^3 to 10^4 kb. Into this gap you are assigning a single gene of 100 bp, or an undefined cloned sequence ranging in size from 10 to 20 kb. At the most you are dropping 20 kb into a 5000 kb gap.

A subband on the human Y may have an even wider resolution span than 5×10^3-10^4 kb. The Y chromosome studied with medium resolution banding (350 bands per genome) has six bands. This number increases only to nine or 10 with high resolution banding (1000 bands). Ellen Magenis at the University of Oregon has some high-resolution studies of the Y in which the idiogram reveals up to 15 bands. In general the small size of the Y and the infrequency of rearrangement has limited *site-specific* mapping by in situ hybridization and translocation mapping with use of human-mouse cell hybrids. However, as more genes are isolated and cloned it will become important to map them to a specific site on a chromosome, and ultimately to a specific nucleotide sequence on a chromosome. At that point we will have bridged the gap between cytogenetics and molecular genetics.

Regarding the second question, location of 4B-2 sequences (DYS 15) were thought initially to be closer to the Y centromere and in the region of the "spermatogenesis factor" described by Tiepolo and Zuffardi,[1] as indicated by Dr. Sarto. Our work and that of others suggest that the 4B-2 sequences are clearly in the Yq11 region but distal to both the actin (ACT 2) and argininosuccinate synthetase (ASSP6) pseudogene sequences on the Y long arm. Recently Wolfe et al.[2] have been able to isolate a centromeric repeat family of DNA sequences that have Y specificity (centromeric Y-alphoid repeats). These sequences in the Y centromeric region are able to detect Y chromosome DNA down to a concentration of 50 ng of male DNA. Their centromeric location makes these sequences ideal for identifying tiny chromosomal fragments as Y chromosome DNA.

The third question, regarding detection of male DNA in maternal blood, is difficult for me to answer because I do not know exactly the number of fetal cells that one might find in the maternal circulation in an average pregnancy. As I indicated earlier, the repetitive copy pS4 probe will detect 2.5 ng of normal male DNA in 997.5 ng of normal female DNA. This represents 1 part male DNA to 400 parts female DNA with 1 μg of total DNA in each lane or well. If one increased the DNA in the lane to 10 μg, then one should be able to increase the sensitivity to 1 part male DNA in 4000 parts female DNA. If each cell has approximately 6 to 10 pg of DNA, then this roughly equates as one cell in 4000. There is a limit to the sensitivity of the probe because ≈50 copies of the pS4 sequences are located on autosomes compared to ≈500 copies on the human Y. As one increases the total concentration of DNA, the 2.3 kb band may begin to appear in situations in which the DNA is completely 46XX, due to these 50 autosomal sequences.

Second, the pS4 probe will not detect Y chromosomes that are deleted of C-bands.

The 4B-2 sequences are single copy, unique to the Y chromosome. The only technical limitations of this probe are the requirement for a larger sample of DNA, usually 7 to 10 μg in each lane, and the Y chromosome must have the 4B-2 sequences.

The centromeric Y-alphoid sequences, as I have indicated, will detect down to 50 ng of male DNA in a sample not containing other genomic DNA. One of the practical clinical limitations of the alphoid Y-specific family may be that 20,000 copies are present in the rest of the genome. An *Eco* RI 5.5 kb fragment appears to be specific for the Y-alphoid repeat family. However, if female and male DNA were mixed together similar to our dilutional experiments with pS4 there is some concern that autosomal DNA may obfuscate the 5.5 *Eco* RI band. This experiment has not yet been done but would be of obvious interest to the obstetrician.

It is possible that the detection of male DNA in fetal blood may lose some of its clinical significance in the years to come. DNA probes in the form of restriction fragment linked polymorphisms are available for the two most common X-linked disorders—hemophilia (Factor VIII deficiency) and Duchenne's muscular dystrophy. Patients may prefer molecular analysis of am-

niocytes for definitive diagnosis of the male fetus at risk.

In reply to the question about whether we do prophase chromosome studies, all of our patients and their available fathers (12 of 20) were karyotyped by means of G-, C-, and Q-banding. We experimented with distamycin in some of our 10 subjects with acentric fragments (n = 4) and one subject (No. 19) with a tiny metacentric Y suspicious for 45X/46,X, i (Yp). The latter was not helpful, so we moved to our molecular analysis once we had repeated our cell counts for coordinating the molecular results.

The small size of the Y chromosome has made karyotypic definition of translocations and deletions difficult. In fact, the small size of the Y limiting the cytogenetic definition of rearrangements and the absence of extensive recombination has hindered the regional localization of genes and gene sequences on the Y. The transition from conventional karyotyping at 250 to 350 bands to high-resolution chromosome analysis at 1200 bands adds only 4 or 5 new bands to the Y. The patients in category C (C_1 and C_2) would be candidates for high-resolution chromosome analysis. However, in the absence of some reference band or bands we felt that high-resolution chromosome analysis would not clarify the character of these minute fragments. At the time we optimistically thought that our DNA probes would do this for us. As it turned out, seven of the 10 variant chromosomes in category C subjects (category C_2) remain undiagnosed. We are waiting for our centromeric Y-specific probe, but we would be happy to forward the cell lines to you for high-resolution chromosome analysis.

The fifth question concerned whether part of the Y chromosome was related to oncogenesis and testicular determinant genes, what part of the Y is oncogenic, and whether this area or gene sequences *overlap* with testicular determining genes. This is difficult to answer. It is perhaps easier to answer the question of overlap versus exclusivity first. On the basis of phenotype-karyotype-tumor correlations, it would appear that gene sequences encoding tumor are on many occasions distinct from gene sequences encoding for testicular differentiation. The 45,X/46,XY patient without testis but with *bilateral rudimentary streaks* who develops a tumor must not have de facto functional genes for testicular differentiation. Magenis and her group in Oregon describe a phenotype female 46,X,del (Y) (p 11.2 → pter) who developed a gonadobastoma in place of one of her rudimentary streak gonads.[3] The area Y p 11.2 → pter is presumed to contain the "critical" testicular determinant genes. This child, though lacking these sequences, developed a tumor. Although oncogenesis may be mediated through sequences other than testicular determinant genes, no oncogene has been identified on the human Y chromosome. The closest oncogene is a human cellular homolog of the Harvey murine sarcoma virus, HRAS2, which has been tentatively assigned to the long arm of X. The presence of this oncogene on X reminds us that the localization of genes for testicular differentiation and the mechanism through which they encode for testis is still unresolved. The majority of investigators continue to pursue the classical approach that "critical genes for testicular differentiation" are encoded and transcribed from the Y chromosome itself. The majority of the available molecular data obtained from studies of 46,XX males, 46,XX true hermophrodites, and 46,XY gonadal dysgenesis suggests that this approach should and seems to be rewarding.

A minority group of investigators, impressed by the lack of Y transcripts, have turned their attention to the X chromosome. Their theories have been bolstered by the discovery of gene sequences in the heterogametic-banded Krait snake (BKM sequences), which are important in sexual differentiation and have been conserved in every species up through man. The only startling finding by Metzger et al.[4] in the Erickson group at Ann Arbor is that these same sequences in man are not on the Y chromosome but on the X. These data suggest that the Y chromosome in man may play only a regulatory role, and active transcripts producing gene products important in sexual differentiation may be coming from the BKM sequences on the maternal derived X.

Our group in Augusta under Jay Tischfield has begun to isolate mRNA from early stages of human development, in order to determine by Northern blotting whether hybridization to our previously described Y probes occurs. Clear hybridization should suggest that Y DNA is actively transcribing during early development, if not in the adult. If hybridization does not occur, then one may need to look for transcripts that hybridize with the BKM sequences from the X chromosome depending upon which theory for sexual differentiation you advocate.

I would now like to respond to the questions of Dr. Sherman Elias. He asked whether we have studied any X-linked or sporadic 46,XY gonadal dysgenesis patients. To date we have studied seven patients with sporadic 46,XY gonadal dysgenesis (Swyer's syndrome). However, the DNA probes that we have used all involve DNA sequences localized to the long arm of the Y chromosome. DNA from these seven patients reveals normal male-specific bands with pS4, 4B-2, and more recently the argininosuccinate synthetase sequences. The latter, symbolized as ASSP6, are pseudogene sequences located more proximal and closer to the centromere on Yq than the 4B-2 and pS4 sequences. We and others have avoided the 46,XY gonadal dysgenesis subjects where vertical transmission with X-linked inheritance is suspect from pedigree analysis. The suspicion in these familial cases is more directed at an X-linked gene, and one may not anticipate any Y DNA abnormalities.

The critical deletions or mutations in 46,XY gonadal dysgenesis are probably on Yp. David Page at the Whitehead Research Institute in Boston has identified a deletion of certain cloned Y sequences in three of four 46,XY gonadal subjects studied, and interestingly

enough, the same deleted sequences are the ones present in 46,XX sex-reversed males. In approximately 75% of 46,XX males studied to date hybridization with single copy short arm Y probes has been demonstrated. Single copy Y DNA has also been identified in a 46,XX true hermaphrodite. The quest is obviously for a sequence or family of sequences that are critical for normal sexual differentiation.

We did not do any H-Y antigen studies in our patients. This area remains so controversial that results are difficult to interpret. In fact, the Y chromosome is singularly lacking in known gene products. Recently an antibody 12E7 reacting with a cell surface antigen has been identified, and the antigen appears to be a Y gene product. The gene itself is referred to as MIC2Y. The lack of other gene products to date has created some concern or skepticism as to whether such products actually exist. On the other hand, many cloned sequences have been mapped to Y but without any specific function or gene products.

I believe that your interest in the molecular basis for sporadic 46,XY gonadal dysgenesis is a very relevant one. These individuals as studied by most investigat have cytologically normal Y chromoso nes. Since th gonadal phenotype is bilateral rudimentary streak nads, they would be apt candidates for a molecu deletion involving the critical testicular determin genes as Page has found in a small series of patien

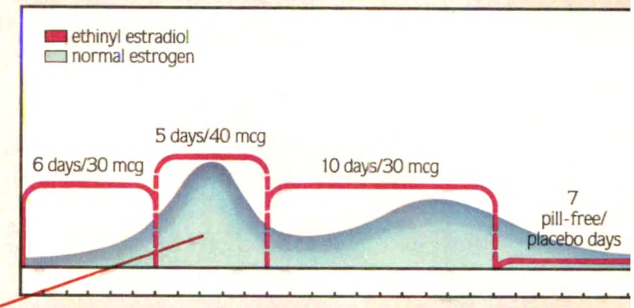
Bound volumes available to subscribers

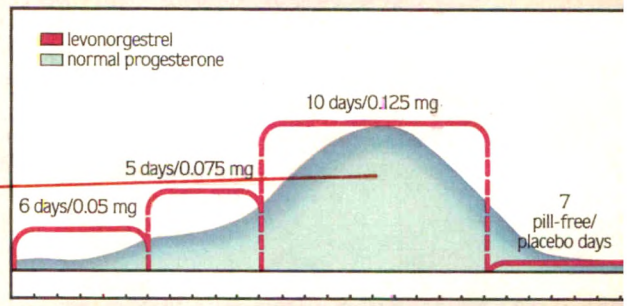
Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.



Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

THE TEXTBOOK TRIPHASIC

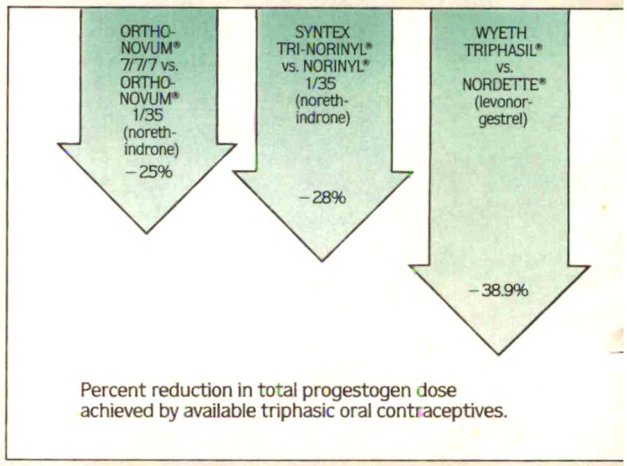
1986 EDITION



IT REDUCES DOSE... BUT NOT PERFORMANCE

TRIPHASIL® adjusts both estrogen and progestogen to follow a woman's normal hormonal patterns.

Estrogen—increased during periovulatory period



Estrogen is increased during the periovulatory period assure contraceptive efficacy. Progestogen is increas throughout the secretory period for added endometr support when it's most needed.

Progestogen—increased for added endometrial support

TRIPHASIL® offers the lowest total estrogen content any phasic regimen and the greatest reduction in pr gestogen—in fact, the lowest total hormonal dose of a combination oral contraceptive—without compromisi performance.

Lowest total dose of any combination O.C.

Percent reduction in total progestogen dose achieved by available triphasic oral contraceptives.

THE TEXTBOOK TRIPHASIC
1986 Edition

NEW STUDIES CORROBORATE INITIAL FINDINGS OF MINIMAL METABOLIC IMPACT

Numerous studies now support the conclusions of initial investigators—that low dose TRIPHASIL® can be expected to have minimal impact on lipid metabolism.

↑ Increased ↓ Decreased ⇄ No Significant Change □ Not Tested

INVESTIGATOR	(MONTHS)	TOTAL CHOLESTEROL	TRIGLYCERIDES	HDL CHOLESTEROL	LDL CHOLESTEROL
GASPARD[1]	6	⇄	⇄	⇄	⇄
VERMEULEN[2]	6	⇄	⇄	⇄	⇄

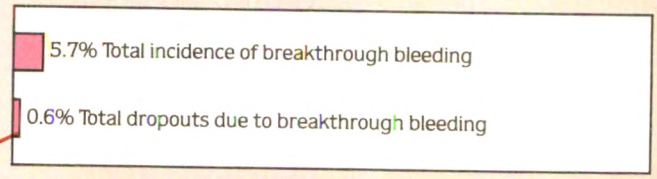
LARSSON-COHN[9]	6	⇄	↑	⇄	

No significant lipid impact up to 18 months of use

Throughout this extensive battery of studies,[1-9] the TRIPHASIL® formulation produced no significant change in total cholesterol, HDL cholesterol or LDL cholesterol. Some studies did not show a significant increase in triglycerides, while others did. TRIPHASIL® has also been shown to have no significant impact on carbohydrate metabolism[6] or blood pressure means.[10]

No significant impact on BP means or carbohydrate metabolism



See Wyeth Rep for study details

Triphasil®
Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen
Wyeth
21- and 28-day regimens
A study in documented performance

See important information on last page.

LOW INCIDENCE OF BREAKTHROUGH BLEEDING ENCOURAGES PATIENT ACCEPTANCE

In clinical trials involving 35,036 cycles of TRIPHASIL® use,[10] patients experienced a high degree of contraceptive efficacy and an extremely low incidence of breakthrough bleeding.*

This resulted in an excellent record of patient acceptance. Only 0.6% of patients discontinued their TRIPHASIL® regimen because of breakthrough bleeding.

Only 0.6% dropouts due to BTB

PREFERRED PACKAGING

TRIPHASIL® offers easy-to-remember Day 1 start, with no need for back-up contraception during the first cycle when taken as directed.† The discreet, reusable compact —preferred by patients and physicians[11]—helps patient stay on schedule, month after month.

No need for back-up contraception in 1st cycle

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives.

†No first-cycle pregnancies in 3,546 women using no additional protection. In worldwide postmarketing experience, only one first cycle pregnancy has been reported in the literature. (Graham H: Letter to Editor, *Br Med J 284*:422, 1982.) **For dosage and administration, see brief summary on last page.**

Only Triphasil® Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

Wyeth

21- and 28-day regimens

A study in documented performance

©1986, Wyeth Laboratories

IN BRIEF:
TRIPHASIL®—6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen)—Triphasic regimen.

Indications and Usage—TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems*—An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly ot types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, fo any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of fi missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becomin pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinician recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed wh on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in use increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in t 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously ha had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infa has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not l prescribed for longer than 1 year without another physical examination and Pap smear.

2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depressio recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administere with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woma becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecti the elevated TBG; free T4 concentration is unaltered.

d. Decreased pregnanediol excretion.

e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenyto sodium, ampicillin and tetracycline.

Carcinogenesis—See Warnings section for information on carcinogenesis.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (se Warnings):thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatmen edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation wh given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergi mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepeni intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the associa has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, change appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multifo erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—For maximum contraceptive effectiveness, Triphasil must be taken exactly as directe and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medicatio or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information in package insert.

Partial purification of relaxin from human seminal plasma

Gerson Weiss, M.D., Laura T. Goldsmith, Ph.D., Cy Schoenfeld, Ph.D., and Richard D'Eletto, B.S.

New York, New York

Human seminal plasma contains approximately 50 ng/ml of relaxin (specific activity = 1.3 ng/mg protein). During preliminary purification, semen plasma was delipidated, rehydrated, and loaded onto small octadecyl silica columns that were eluted with a TEAF/acetonitrile gradient system. Results were monitored by radioimmunoassay. The resultant partially purified human relaxin demonstrated biologic activity in the rat uterine segment bioassay. Nine liters of semen plasma was delipidated, rehydrated in TEAF, and subjected to high-performance liquid chromatography by a step gradient followed by a linear gradient. The active eluate was further purified by ion exchange chromatography. Pooled recovery fractions provided a total of 45.8 μg of relaxin. An aliquot flash evaporated and desalted by gel filtration chromatography provided 1.85 μg of relaxin in 25.2 mg protein, specific activity 73.4. This material is being used as immunogen in the production of antihuman relaxin antibodies by monoclonal technique. Our procedure represents the first and only successful partial purification of human relaxin to yield sufficient quantity and purity for antibody production. (Am J Obstet Gynecol 1986;154:749-55.)

Key words: Relaxin, semen, HPLC

Relaxin was discovered in 1926 by Hisaw.[1] It was shown to be a hormone that modifies the maternal reproductive tract during pregnancy. The major source of relaxin for experimental use is porcine ovaries, structures particularly rich in relaxin and readily available from abattoirs. Since porcine relaxin is devoid of tyrosine and histidine, amino acids necessary for iodination, development of a radioimunoassay (RIA) was delayed until a technique was developed to radiolabel the molecule.[2] This allowed several laboratories to establish RIAs for relaxin. The structure of porcine relaxin was simultaneously determined by two laboratories.[3, 4]

In 1976 our laboratory clearly showed that relaxin is a human hormone of pregnancy, produced by the corpus luteum.[5] The primary structure of human relaxin, as determined by recombinant DNA technology, significantly differs from that of porcine relaxin.[6] Human relaxin has never been purified from a biologic source. This is because its concentration is relatively low, even in the corpus luteum, the richest source in humans. Starting material for purification is difficult to obtain. The hormone is a small molecular weight peptide of approximately 6000 daltons. It is lipophilic and has a high isolectric point. These characteristics result in its property of adhering to laboratory ware and other proteins. For example, we have determined that partially purified human relaxin adheres to and will not elute from certain kinds of filters. Its adherence to other substances prevents its clean precipitation by ammonium sulfate after dilipidation. Rather, it precipitates in a very broad peak with some of the hormone precipitating in all concentrations of ammonium sulfate. Similar problems occur when attempts are made to precipitate relaxin by graded ethanol concentrations after delipidation.

In 1980 immunoreactive relaxin was determined to be present in human semen plasma.[7] We confirmed this observation and demonstrated the seminal relaxin to be biologically active in the guinea pig pubic symphysis palpation assay.[8] Relaxin concentration in semen plasma averages 50 ng/ml compared with approximately 1 ng/ml in serum from pregnant women. Since semen plasma is plentiful compared with other human relaxin sources, we could use this as a starting material for purification and accept low yields caused by the molecule's properties. Our strategy is to isolate and purify human semen relaxin to a level of purity sufficient to produce monoclonal antibodies to human relaxin, monitoring purification with both RIA and bioassay. The antibody can then be used to further purify human relaxin by affinity chromatography. The purified relaxin as well as the antibodies could then be used as research tools. In this report we described the partial purification of human semen relaxin to be used as an immunogen.

From the Department of Obstetrics and Gynecology, New York University School of Medicine and Fertility Research Laboratory.

Supported in part by National Institutes of Health grant HD 12395 and a grant from the Mellon Foundation.

Presented by invitation at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.

Material and methods

Semen plasma. Semen plasma for starting material to be used in relaxin purification was obtained from a fertility laboratory. Semen was collected by masturbation after 3 to 5 days of abstinence. The samples were allowed to stand at room temperature for approximately 3 hours for completion of semen analysis. Samples were then centrifuged at 600 × g for 10 minutes, the pellet was discarded, and the semen plasma was pooled and stored frozen at −20° C.

Assays. Relaxin was measured by RIA with the use of rabbit antiporcine relaxin antibody R6, developed by O'Byrne and Steinetz.[9] ^{125}I polytyrosylated porcine relaxin was used as ligand and purified porcine relaxin (CMa') as standard. All results are expressed as nanograms per milliliter of immunoreactive equivalents of porcine relaxin. The sensitivity of this assay is 50 to 100 pg per tube. The interassay coefficient of variation is 12.9% and intraassay coefficient of variation is 6.1%. The average precision of the assay is 13.9%. All samples were measured in triplicate.

Protein was determined by the method of Lowry et al.[10]

All glassware was silanized with Prosil-28 (SCM Chemicals, Gainesville, Florida) before use.

The rat uterine horn segment bioassay for relaxin with in vivo estrogen and progesterone pretreatment has been described in detail.[11] Immature female Long-Evans rats were treated subcutaneously with 1 μg of estradiol benzoate in sesame oil for 3 days. Two milligrams of progesterone in sesame oil was injected subcutaneously on days 2 and 3. The animals were killed on day 4 and their uteri isolated. Uterine horn segments were mounted in a double-jacketed organ bath attached to an isometric smooth muscle transducer. Electrodes from a direct-current stimulator were positioned so that one was free in the bath and the other touched the uterine horn segment. The muscle was bathed in 5 ml of modified Locke solution. Spontaneous contraction patterns were observed and a baseline contraction pattern was established with electric stimulation of 5 V, 60 Hz, for 5 seconds every minute. After contraction patterns were established the bath was changed and 5 ml of modified Locke solution containing the substance to be tested was added. Baseline and stimulated contractions were then monitored. At the end of the experiment the uterine segment was washed in modified Locke solution alone three times and contractions were again observed to demonstrate that inhibition of contractions was not a nonspecific toxic effect.

Delipidation. The first step in all purification protocols was delipidation. Semen plasma was extracted with 10 vol of cold acetone. The supernatant was decanted and discarded. The precipitate was then diluted with 10 original vol of hexane and the supernatant discarded. The precipitate was then extracted with 10 vol of acetone and saved by suction filtration on Whatman No. 541 filter paper. The precipitate was air dried overnight at room temperature and dissolved in deionized water. The insoluble material was removed by centrifugation at 1000 × g for 10 minutes. The supernatant was lyophilized and stored at −20° C. In the large-scale purification scheme, the acetone wash was acidified with 0.1N HCl. All reagents used in purification were high-performance liquid chromatoagraphic (HPLC) grade.

Octadecyl silica (ODS) purification—small scale. The powdered delipidated semen plasma from 100 ml of semen plasma was dissolved in 500 ml of 0.25N TEAF, pH 3.0. This was divided into 29 parts and loaded on disposable Sep-Pak ODS columns, 191 mg powder/17.2 ml/column. The columns had been previously activated with 10 ml of methanol and equilibrated with 10 ml of 0.25N TEAF, pH 3.0. The eluate was recirculated and reloaded for a total of 10 times to ensure complete adsorbance to the column. After loading, each Sep-Pak was washed with 10 ml of TEAF. This was followed by a wash with 10 ml of 20% acetonitrile (CH_3CN)/80% TEAF. This was followed by a wash with 9.5 ml of 40% CH_3CN/60% TEAF. Most of the relaxin eluted in the last 9 ml of this wash. The corresponding fractions from all Sep-Paks were combined and assayed for relaxin.

HPLC was carried out on a Supelcosil semipreparatory (10 mm by 25 cm) ODS column containing 5 μm of particles with 10 nm of pores (catalog No. 5-8358, Supelco Inc., Belafonte, Pennsylvania). The chromatograph used was a Beckman model 324-MP advanced gradient liquid chromatograph with two solvent delivery pumps and a CRT controller (Beckman Instruments, Inc., Fullerton, California). The column effluent was monitored at 254 nm with a Hitachi variable wavelength spectrophotometer, model 155-10, equipped with a high-pressure flow cell. The recording was made on a Kipp & Zonen dual pen strip chart recorder (Kipp & Zonen, Bohemia, New York) set on two absorbance units full scale, with a chart speed of 0.5 cm/min. Fractions were collected at 1-minute intervals with a Gilson model 201 fraction collector (Gilson Medical Electronics, Inc., Middleton, Wisconsin) into borosilicate glass tubes.

The column was equilibrated with 12% CH_3CN/TEAF. The pooled Sep-Pak fractions were diluted with 2 vol of TEAF to restore CH_3CN to 12% a concentration at which relaxin completely adsorbs to the column. Sample loading was accomplished via the aqueous solvent delivery pump. This eliminates the need for drying the Sep-Pak fraction, rehydrating, and clarifying the solution, steps that result in loss of relaxin. After loading, the pump and columns were flushed with 100 ml of 12% CH_3CN/TEAF followed by 100% TEAF.

Table I. Partial purification of relaxin from 100 ml of human semen plasma

Procedure	*Total activity (ng)**	*Protein (mg)†*	*Specific activity (ng/mg)*	*Yield (%)*	*Purification (fold)*
Original semen plasma	8860	4343	2.0	100	(1.0)
Acetone, hexane extracted semen plasma	5150	1525	3.4	58.1	1.7
Sep-Pak eluate	1690	36.5	46.3	19.1	23.2
HPLC eluate	1450	22.5	64.4	16.4	32.2

*Total activity by RIA.

†Total protein determined by the method of Lowry et al.[10]

Relaxin was eluted by means of a linear gradient of CH_3CN/TEAF, increasing CH_3CN from 12% to 22% in the first minute. In the next 21 minutes the CH_3CN was increased to 50%. Flow rate was 4.73 ml/min. Fractions were collected in borosilicate glass test tubes (12 by 75 mm, RTU; Becton Dickinson, Parsippany, N.J.). Relaxin eluted at 77.5 ml. Relaxin was measured by RIA directly, aliquoting the mixture into 0.5 ml of RIA buffer (0.01 mol/L phosphate-buffered saline solution with 1% ovalbumin, pH 7.0).

Large-scale purification. Nine thousand ninety-four milliliters of pooled semen plasma containing 461.5 μg of immunoactive relaxin and 343.1 gm of protein was extracted with acid acetone, hexane, and acid acetone. The precipitate was dried and rehydrated with 0.25N TEAF, pH 3.0. This was clarified by ultracentrification at 40,000 rpm (250,000 × g) for 1 hour.

Preparatory octadecylsilyl silica high-pressure liquid chromatography. The Prep LC/System 500 (Waters Associates, Milford, Massachusetts) with ODS Prep-Pak 500 cartridge, 5.7 by 30 cm, was activated with 4 L of methanol and equilibrated with 4 L of TEAF. The delipidated semen plasma was loaded onto the Prep-Pak and recirculated for 8 hours at a flow rate of 250 ml/min. Elution by a step gradient proceeded at a flow rate of 100 ml/min. Four liters of 0.25N TEAF, pH 3.0, was used as the initial wash. The second wash was 6 L of 20% CH_3CN/80% TEAF. The next wash was 8 L of 40% CH_3CN/60% TEAF, the first 5 L collected in 500 ml fractions and the remaining 3 L collected as one fraction. A final wash of 4.5 L of 60% CH_3CN/40% TEAF was performed.

Fraction 2 of the 40% CH_3CN/60% TEAF step gradient, containing 53% of the load and 80% of the total recovery, was filtered on a 0.45 μm pore size hydrophilic Millipore Durapore membrane (No. HVLP04700, Millipore/Continental Water Systems, Bedford, Massachusetts) to remove precipitated protein that formed during storage at −20° C. The solution was diluted to 4 L in 0.25N TEAF, pH 3.0. The Prep-Pak was equilibrated with 4 L of 5% CH_3CN/95% TEAF, loaded with the diluted fraction 2 and recirculated for 30 minutes. A linear gradient of 10% to 50% CH_3CN/30 minutes was chosen. Fractions were collected, with fraction 1 containing 970 ml, fractions 2 through 25 containing approximately 250 ml each, and fraction 26 containing 828 ml. Fractions 13 through 17 were pooled, with a total volume of 1278 ml.

Ion exchange chromatography. After preliminary study, 1041 ml of the pooled fractions 13 through 17 were flash evaporated to 83 ml, ionic strength 0.2 mol/L. This was diluted fivefold with water and the pH adjusted from 3.0 to 5.0 by dropwise addition of triethylamine to a volume of 415 ml, ionic concentration 0.093 mol/L. During pH adjustment, a precipitate formed that was removed by ultrafiltration at 250,000 × g for 60 minutes. The supernatant had a pH of 5.0, ionic strength of 0.1 mol/L, and a volume of 405 ml. There was no measurable loss of relaxin in the precipitate.

Carboxymethyl Fractogel (Fractogel TSK CM-G50-S Merck Chemical Division, Rathway, New Jersey) was equilibrated in 0.05 mol/L ammonium acetate, pH 5.0, and packed in a Pharmacia K 50/30 glass column (5 by 15 cm, bed volume 294.5 ml) fitted with Pharmacia A-50 flow adaptors at both ends (Pharmacia Fine Chemicals, Piscataway, New Jersey). Three hundred ninety-five milliliters was pumped onto the column with a Pharmacia P-4 peristaltic pump, flow rate 2 ml/min. Relaxin was not detected in the column effluent. Unadsorbed proteins were washed off with 0.05 mol/L ammonium acetate, pH 5.0. Relaxin was eluted from the column with a 0 to 1 mol/L NaCl linear gradient in 0.05 mol/L ammonium acetate, pH 5.0. Three-minute fractions (6.1 ml) were collected. After 99 fractions were collected, baseline optical density at 280 nm was not reached. Elution was continued until 26 additional samples were collected and the baseline had reached its pregradient elution level. Relaxin was detectable in the last fraction indicating that some relaxin remained on the column. Elution was continued isocratically with 1 mol/L NaCl in 0.1 mol/L of ammonium acetate, pH 5.0, for another 75 fractions. Relaxin-containing fractions were combined into eight separate pools.

Gel filtration chromatography. Size exclusion chromatography used Sephadex G-50 (fine) packed in a Pharmacia K-26/100 glass column (2.6 by 100 cm; bed

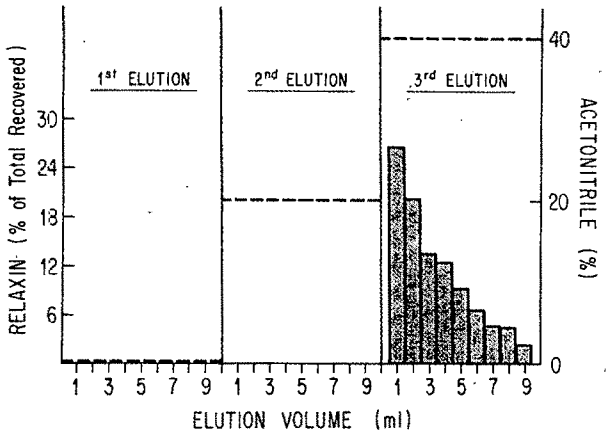

Fig. 1. Triple-step gradient of CH_3CN/TEAF used in the elution of human semen relaxin from a Sep-Pak.

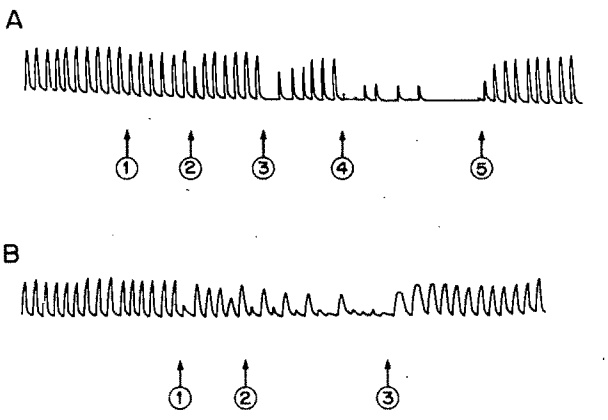

Fig. 2. Effect of relaxin on electrically stimulated rat uterine horn segments. In *A*, 2 ng of porcine relaxin (NIH-R-P1) is added at *arrows 1-4*. *Arrow 5* indicates a wash. In *B*, 8.8 ng of partially purified human semen relaxin is added at *arrows 1 and 2*. *Arrow 3* indicates a wash.

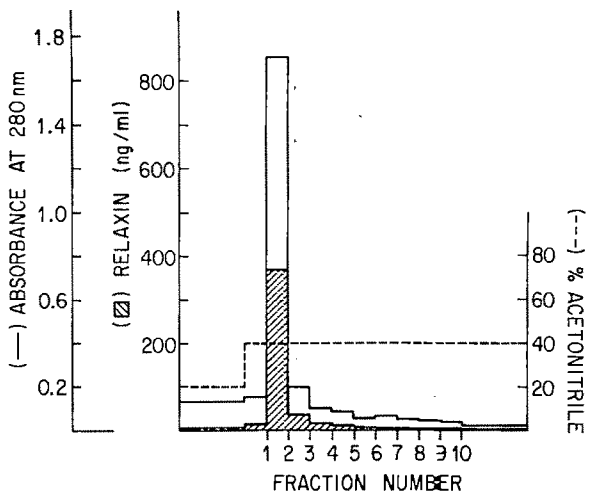

Fig. 3. Multiple-step gradient elution of human semen relaxin from a Prep-Pak with CH_3CN/TEAF. The Prep-Pak load was solubilized delipidated powder from 9094 ml of human semen plasma.

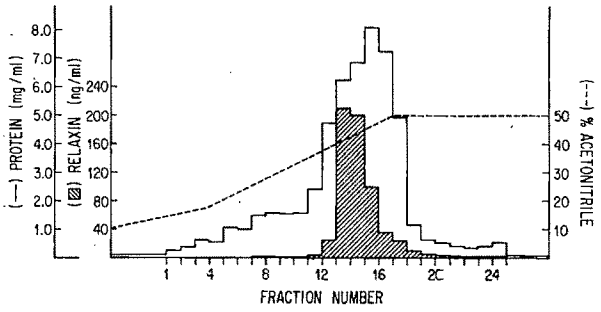

Fig. 4. Rechromatography by a linear gradient of CH_3CN/TEAF on the Prep-Pak of fraction 2 from the step gradient (Fig. 3).

volume 530 ml) fitted on top with a Pharmacia A-26 flow adaptor. The column was equilibrated in 0.01 mol/L ammonium acetate, pH 5.0, at a flow rate of 2 ml/min. All fractions were collected at 4-minute intervals in 13 by 100 mm borosilicate glass RTU test tubes. The column was presaturated with 0.1% bovine serum albumin. The load solution, 20.85 ml, flash evaporated from 468 ml taken from a preliminary recovery from ion exchange chromatography, contained 5.06 μg of relaxin, with 221.8 mg of protein, specific activity 22.82 ng/mg.

Results

Small-scale purification. The results of the small-scale purification of 100 ml of semen plasma can be seen in Table I. The results of the step-gradient elution of relaxin from a Sep-Pak can be seen in Fig. 1. No relaxin is eluted by the 20% CH_3CN/80% TEAF wash. Most of the relaxin is eluted in the 40% CH_3CN/60% TEAF wash.

The pooled mobile phase from the relaxin eluate from HPLC was evaporated under vacuum and lyophilized four times to completely eliminate all solvent. This material was rehydrated and applied to the rat uterine horn segment relaxin bioassay. As can be seen in Fig. 2, human seminal relaxin purified by these methods is active in this assay. The high sensitivity of this assay compared with other bioassays of relaxin allows its use in the monitoring of purification of human semen relaxin.

Large-scale purification. After delipidation, the pooled semen plasma contained 437.9 μg of relaxin. This was chromatographed by Prep-Pak HPLC by a step gradient. The results are seen in Fig. 3. Fraction 2 contained 232.3 μg of relaxin/11.1 gm protein, specific activity 20.93 ng/mg.

The results of Prep-Pak HPLC with a linear gradient are seen in Fig. 4. The load of relaxin was 204.6 μg. Fractions 13 through 17 contained 198.8 μg of relaxin and 8.95 gm of protein, specific activity 22.21 ng/mg.

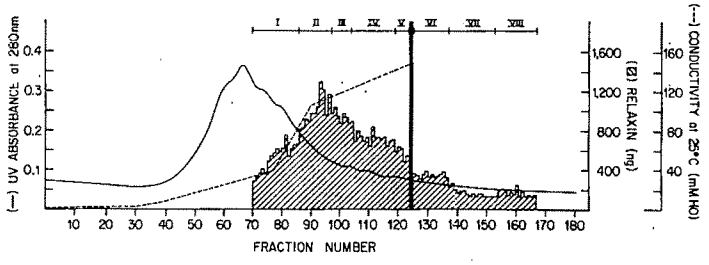

Fig. 5. Chromatography of Prep-Pak purified human semen plasma by ion exchange chromatog raphy on carboxymethyl Fractogel TSK with the use of an NaCl gradient. The *vertical arrow* indicates where the second session of column elution started. *Roman numerals* signify pooled fractions.

The results of ion exchange chromatography of 1041 ml of pooled fractions 13 through 17 from HPLC are shown in Fig. 5. Recovery of fractions 70 through 124 contain 37.82 μg of relaxin and 0.737 gm of protein, specific activity 51.32 ng/mg. The purest pool was VIII, containing 1.79 μg of relaxin/5.95 mg of protein, specific activity 301 ng/mg. This is a 13.5-fold increase in purity over that of the column load. If pools III through VIII were arithmetically combined, the relaxin content of this pool would be 29.1 μg of relaxin/138.74 mg of protein, specific activity 210.9 ng/mg. The estimated total recovery, if the entire quantity of starting material had been pumped through all of the steps, would be 10.67%.

Gel filtration chromatography. The desalting procedure was run with the eluate of 468 ml from pooled recovery fractions 57 through 135 of a preliminary ion exchange chromatography run. These results can be seen in Fig. 6. Pool II contains 1.85 μg of relaxin and 25.2 mg of protein, specific activity 73.4 ng/mg, with an ionic strength of 0.01 mol/L. Pool III contained 0.458 ng of relaxin/1.04 μg of protein, specific activity 440.4 ng/mg. However, this pool had an ionic strength of 0.43 mol/L, indicating that it was not salt free. Pool II is being used for monoclonal antibody production.

Comment

To our knowledge, this article reports the first successful partial purification of human relaxin from a biologic source in sufficient quantity and purity for antibody production. Our attempts at purification of human seminal relaxin have provided several useful techniques to decrease procedural losses. These include keeping the relaxin in acidic solution and silanization to decrease adherence to labware. Avoidance of drying and filtering partially purified relaxin, but rather maintaining it in a dissolved state, also helps decrease procedural losses. For example, in an earlier purification protocol we filtered relaxin on a Millex GV filter, a polyvinylidene difluoride hydrophilic membrane contained in a disposable polystyrene holder. We first tested the filter with porcine relaxin and it allowed passage without loss. However, this filter unit retained 75%

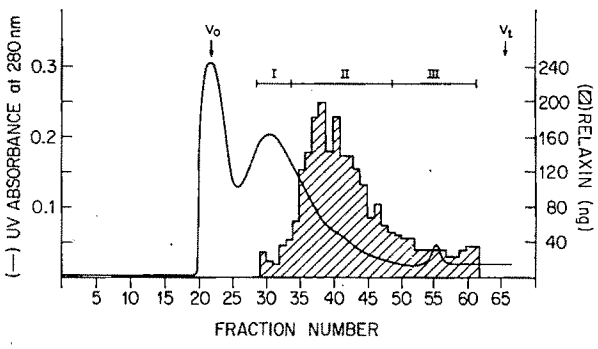

Fig. 6. Desalting of CM Fractogel TSK–purified human semen plasma on a Sephadex G-50 (fine) column. *Roman numerals* indicate pooled fractions. *Vo*, void volume; *Vt*, total volume.

of the human relaxin. We were unable to elute this relaxin by any technique.

Our procedures will provide experience in devising techniques for the purification of relaxin-like peptides from other sources, some with much lower concentration or availability.

It is likely that there will be considerable microheterogeneity in our relaxin preparation. Semen plasma contains many proteolytic enzymes such as amino and carboxypeptidases, which may partially degrade the native hormone but may not affect its biologic activity. Porcine relaxin can accept signifigant loss of the C-terminus of the B chain without loss of biologic activity.[12]

Hudson et al.[6] have shown that there are two genes for human relaxin as identified from a human genomic library. These two genes encode markedly different relaxin peptides. Little is known of the expression of these genes except that one is preferentially expressed by human ovaries during pregnancy. Characterization of seminal relaxin is necessary to determine which gene is expressed in the male. It is tempting to postulate that there is divergent gene expression in the male and female. This possibility can be evaluated by purification of the seminal hormone and comparison of its structure to that of ovarian relaxin. The studies may provide models for the evaluation of the hormonal regulation of gene expression.

The partial purification of relaxin described herein

will provide material for the production of antihuman relaxin antibodies, which, in turn, can be used for final purification of seminal relaxin as well as establishment of human relaxin immunoassays. Antirelaxin antibodies will also be useful tools in determination of the biologic roles of relaxin.

Because of significant primary structural differences, administration of nonhuman (porcine) relaxin to humans has the potential danger of being immunogenic. Human relaxin in sufficient quantities for clinical use will be available only as material generated by recombinant DNA methodology. However, use of the recombinant DNA–derived relaxin will require verification of the structure of the native human hormone.

Discussion

DR. KAMRAN S. MOGHISSI, Detroit, Michigan. Relaxin was discovered almost 60 years ago. It is a polypeptide hormone with a similar structural identity to that of insulin and nerve growth factor. Its main source appears to be the corpus luteum of pregnancy, but it is also produced by the male prostate gland and is found in many target tissues such as cervix, myometrium, decidua, and breast connective tissue. Its principal mechanism of action appears to be the facilitation of remodeling of connective tissue in target organs to allow the necessary changes in organ structure during pregnancy and parturition. Additionally, in some mammals, relaxin inhibits myometrial contractility until near the end of pregnancy.

Possible roles for relaxin in the human include enhancement of sperm motility and penetration into cervical mucus, ovum penetration, implantation of blastocyst, uterine stromal remodeling during pregnancy, the inhibition of premature labor, cervical ripening, and collagen biosynthesis in disorders of collagen metabolism such as scleroderma and arthritis.[1,2]

Porcine relaxin has been well studied and purified. This preparation has been used in most animal experiments and some clinical studies.

The amino acid sequence of a human relaxin derived from the recent identification of a genomic clone for relaxin is now known.[3] Approximately 50% homology between porcine relaxin and this human relaxin exists. Porcine and human relaxins share the same tertiary structure and some of the same amino acid sequences at biologically active sites.

Human relaxin has not, as yet, been purified and the development of a specific assay must await the availability of purified samples of human relaxin for antibody development.

The stated goals of Dr. Weiss and his associates are as follows: (1) purification of relaxin to a sufficient degree so that workable amounts of relaxin-specific antibodies can be obtained, (2) use of the antirelaxin antibodies to prepare affinity immunosorbants that can be used to complete the relaxin purification, (3) sequence of the purified relaxin to determine molecular structure, and (4) use of recombinant DNA methods to batch up adequate amounts of relaxin for clinical studies.

The work presented here deals with only the first item, namely partial purification. The purification of relaxin from seminal plasma is a difficult problem and Dr. Weiss and his colleagues should be complimented for their persistance and their ability to collect "9 L" of semen as their starting material. However, there are severe limitations in the experimental approach used by the authors.

First, the levels of immunoreactive relaxin in human seminal plasma are exceedingly low, approximately 9 μg per 9 L (representing 4300 μg of proteins). Even assuming purification to homogeneity with 100% yield, which would require a 500,000-fold enrichment, the amount of relaxin recovered would be barely sufficient for structural analysis. Dr. Weiss reports a 32-fold purification with only 16% yield after three purification steps. This is certainly not an encouraging result.

Second, the authors plan to use the partially purified relaxin, which contains only 0.006% of total protein as immunoreactive relaxin, as immunogen for an attempt to raise monoclonal antibodies to relaxin. What are the chances of success of this approach? This manuscript contains no data regarding this but I heard from Dr. Weiss that he has been successful in raising antibodies to relaxin. Another question is how does he intend to screen for clones secreting antibodies to relaxin? There is no guarantee that an immunoaffinity resin with an antirelaxin monoclonal antibody would yield relaxin in sufficient yield or purity for structural studies.

Despite these problems, Dr. Weiss and his colleagues should be encouraged to pursue these studies with the hope that their success might lead to the availability of human relaxin and precise identification of its many biologic functions.

Dr. Willard M. Allen, Glenwood, Maryland. People ask me what I do nowadays, and I say I celebrate anniversaries. Actually, the word "progesterone" celebrates its fiftieth anniversary this year. The name relaxin goes back, I suppose, about 10 years more.

When progesterone came on the scene, the majority of scientists thought that relaxin had been buried, thrown away as it were. However, I knew Fred Hisaw very well. As a matter of fact, with one of his previous graduate students in Rochester, I repeated some of his original work including the bioassay, which was performed by the measurement of palpation, really of separation of the symphysis in the guinea pig.

If you are interested in bioassay, this is probably one of the most treacherous of all. The truth of the matter is, though, the reason for Hisaw getting at this originally was that the guinea pig has fetuses that are so large at birth that they could never be born at all unless the symphysis relaxed. The symphysis really does relax to the point where you can actually almost slip an index finger between the two sides of the symphysis. That is real relaxation, and it makes possible the delivery of the fetuses.

Now, we hear about porcine relaxin. Actually, the first relaxin Hisaw ever had came from the corpora lutea of pigs. We called them sows in those days. Nowadays the language gets more elaborate.

Relaxin has never died, and it is really comforting after all these years to know that it is still a hormone that was sidetracked on the road to progesterone. Of course, in Hisaw's laboratory as well as in the Corner-Allen Laboratory in Rochester, the relaxin went down the drain because the steroids that we were both after were not in the fraction that contained relaxin. In fact, Hisaw and Fevold did obtain progesterone a little later than we did. But the fact still remains that nothing in the way of ovarian hormone combinations, that is, estrogens and progesterone, ever produced relaxation of the symphysis of the guinea pig such as Hisaw observed. His original extracts were made with acid alcohol of pigs' corpora lutea. This method extracted both progesterone and relaxin; the relaxin was lost in the purification that finally yielded pure progesterone.

I guess the mystery now is not that there is a hormone but what it does.

Dr. Weiss (Closing). The concentration of relaxin is certainly low in semen, but it is richer in semen plasma than in any other material except for the corpus luteum. The concentration of relaxin in semen plasma was (as stated in the article) 461 μg/9 L. The corpus luteum is relatively inaccessible so there really is no choice but this for determining the structure of the native hormone.

Our yields are low, 10% at the end of the purification to date. The reason for this, of course, is the physical properties of relaxin, making it rather difficult to deal with.

However, we have been successful, as I mentioned, in producing monoclonal antibodies, and the monoclonal antibody should be useful for performing a final purification step on the affinity column.

Another question that was asked was, "Will there be enough for a structural analysis?" If by structural analysis, you mean starting from scratch, separating the chains, and doing a total analysis of both chains, the answer is likely no, but that is not necessary. There are two putative relaxin structures encoded by genes identified from a genomic library. These two putative structures are remarkably different. What would be necessary is simply to take the small amount of hormone that will be available, digest it proteolytically, and essentially "fingerprint" it, determine the structure of small areas, and then compare it with gene A or gene B to determine which gene is expressed in the male. The gene that is expressed in the corpus luteum is known, so by this methodology it certainly is possible to be successful in determining the structure of the male relaxin, determining if it is similar or different from the female relaxin, and deriving appropriate material for further study. If necessary, we probably will have enough material to even immunize a rabbit for polyclonal antibody production. We now have 30 μg of the partially purified material stockpiled for further work. We also have stockpiled another 10 L of human semen, so with what we have learned it is possible to simplify the purification now that there will be an affinity column and provide the material that we need.

Human ovarian oxytocin: Its source and relationship to steroid hormones

M. Yusoff Dawood, M.D., and Firyal S. Khan-Dawood, Ph.D.
Chicago, Illinois

To determine the site of oxytocin in human ovaries and its relationship with ovarian steroids, oxytocin and steroid hormones were measured in ovarian tissues, ovarian vein, and peripheral blood. Corpus luteum had significantly higher oxytocin, estrone, estradiol, and progesterone concentrations than corpus albicans and ovarian stroma ($p = <0.01$ to <0.001). Oxytocin concentrations in corpus luteum correlated significantly with estrone, estradiol, and progesterone. Oxytocin in corpus luteum increased from 14.0 ± 1.8 ng/gm of wet weight in early to 30.8 ± 0.9 ng/gm in midluteal phases ($p = <0.001$). Reverse phase high pressure liquid chromatography showed similarity between oxytocin in corpus luteum and synthetic oxytocin. Ovarian vein draining corpus luteum had significantly higher plasma oxytocin (11.8 ± 1.5 pg/ml) than those without corpus luteum (2.1 ± 0.2 pg/ml) or in the peripheral blood (2.9 ± 0.3 pg/ml) ($p = <0.001$). Oxytocin in corpus luteum correlated significantly with its ipsilateral ovarian vein level of oxytocin, estrone, progesterone, and 17α-hydroxyprogesterone. Our findings demonstrate that oxytocin is present and probably produced in corpus luteum and secreted into its ovarian vein; it may regulate corpus luteum release of progesterone, 17α-hydroxyprogesterone, and estrone. (Am J Obstet Gynecol 1986;154:756-63.)

Key words: Oxytocin, corpus luteum, estrogen, progesterone, luteolysis, luteotropic

In 1910 Ott and Scott[1] discovered the oxytocic action of the corpus luteum when they observed that its extract increased the quantity of milk. This interesting observation was not pursued further until this decade when oxytocin was identified in several species.[2] In primates, oxytocin or an oxytocin-like peptide was shown to be present in human ovaries by two independent laboratories,[3,4] which was later confirmed.[5] Oxytocin was also found to be present in the monkey corpus luteum.[6] The role of ovarian oxytocin on ovarian physiology is not established but based on in vitro studies; postulated functions include both a luteotrophic and luteolytic action.[7] Although cultured bovine[8] and ovine[9] luteal cells have been shown to synthesize oxytocin in vitro, there is no information available on the exact source of oxytocin in the human ovary. Furthermore, the in vivo relationship between ovarian oxytocin and ovarian steroid hormones has not been examined. Therefore a study was carried out to examine ovarian oxytocin and steroid hormones. The objectives of the study were to determine (1) the presence and concentrations of oxytocin or an oxytocin-like peptide in different types of normal human ovarian tissues, (2) the relationship between oxytocin and estrone, estradiol, and progesterone in corpus luteum, and (3) the relationship between corpus luteum oxytocin and oxytocin, estrone, estradiol, progesterone, and 17α-hydroxyprogesterone in the ovarian and peripheral venous blood.

Material and methods

Collection of ovarian tissues. Ovarian tissues were obtained from women undergoing gynecologic operations and who gave consent. The tissues were obtained from the pathologist immediately upon their removal. The decision to remove the ovaries was made exclusively by the surgeon operating on the patient, based on clinical considerations. Sixty-nine ovaries were obtained from 45 premenopausal women who had known last menstrual periods. Women from whom fresh corpora lutea were obtained had regular cycles, and the day of their luteal phase was further established with endometrial dating by the pathologist. To minimize prolonged ischemia of the ovary while hysterectomy was proceeding, the ovary was removed separately at the beginning of the surgical procedure. The ovaries were kept on ice and immediately transported to the surgical pathology laboratory for pathologic examination, where they were weighed and specimens taken for histologic study. After this, the ovaries were dissected to obtain corpus luteum, corpus albicans when available, and ovarian stroma. Thirteen fresh corpora lutea, 18 corpora albicantia, and 49 ovarian stromal

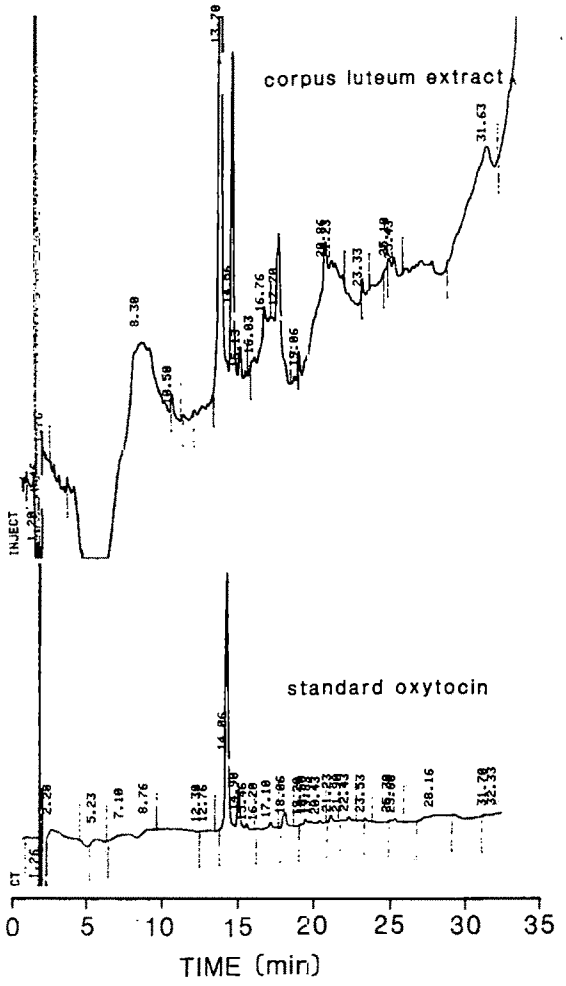

Fig. 1. Reverse-phase high pressure liquid chromatogram of an extract of human corpus luteum (day 24 of the menstrual cycle) compared to standard oxytocin (Sandoz). The samples were chromatographed at room temperature on a Bondapak C_{18} (3.9 mm × 30 cm) column with use of a Waters binary automatic gradient controller (model 680) and the protein peaks detected by a fixed wavelength ultraviolet detector (model 441). The solvent systems used were A (99.9% water and 0.1% trifluoroacetic acid) and B (70% acetonitrile, 29.9% water, and 0.1% trifluoroacetic acid). The gradient used was 2 minutes of 35% B, 37 minutes of 60% B, and 65 minutes of 100% B. A peak corresponding to the standard oxytocin peak is seen with the corpus luteum extract. The retention times of this peak of the corpus luteum extract as well as of standard oxytocin were 14.06 minutes.

tissue samples were available for the study. The tissues were further identified and confirmed histologically. The separated tissue samples were weighed, finely minced in a dish kept cold on crushed ice, homogenized in 0.4 mol/L of acetic acid at 4° C (1 ml of acetic acid per 50 mg of tissue) and centrifuged at 800 × g for 20 minutes. The supernatant was separated, lyophilized, and kept at −20° C until ready for further purification and oxytocin assay.

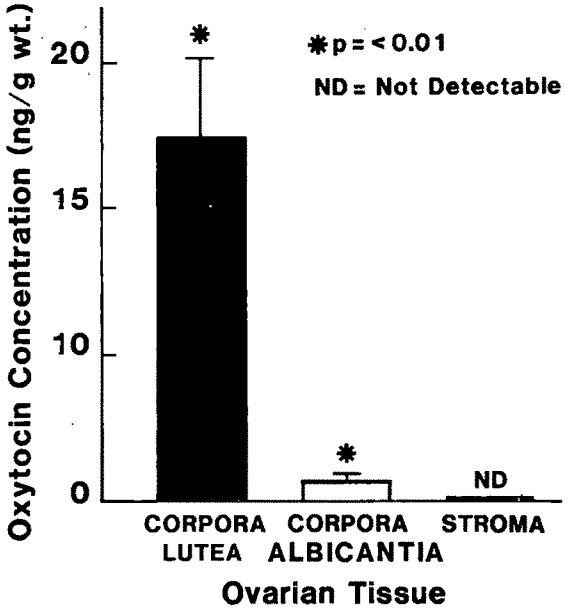

Fig. 2. Mean ± SE concentrations of oxytocin in human corpora lutea, corpora albicantia, and ovarian stroma. Corpora lutea had significantly higher oxytocin concentrations than corpora albicantia (p = <0.01). Ovarian stroma had no detectable oxytocin.

Blood collection. Peripheral venous blood, from the antecubital vein and ovarian venous blood samples, were collected into chilled heparinized vacutainers. When the ovary was to be removed, the infundibulopelvic ligament was isolated and the ovarian vein blood was drawn by venipuncture with use of a No. 19 gauge butterfly needle just before the ligament was clamped. Preliminary studies carried out on oxytocin levels in peripheral venous plasma obtained before premedication and general anesthesia and while under general anesthesia showed no significant effect of the latter on plasma oxytocin. Thus all peripheral blood samples were collected simultaneously with the respective ovarian vein sample. There were eight ovarian vein blood samples draining a corpus luteum, 24 ovarian vein blood samples from ovaries without corpus luteum (10 in the follicular and 14 in the luteal phase), and 28 antecubital vein blood samples (13 in the follicular and 15 in the luteal phase). The blood samples were kept cold, immediately transported to the laboratory in crushed ice, and centrifuged at 4° C to separate the plasma. An aliquot of the plasma was acidified with 0.2 ml of 1N hydrochloric acid for each milliliter of plasma and frozen at −70° C until ready for oxytocin assay. The remaining plasma was also frozen at −70° C for sex steroid hormone assay.

Oxytocin assay. The lyophilized extract from the ovarian tissue was resuspended in 0.4 mol/L acetic acid and passed through an octadecasilicyl silica (Sep-Pak)

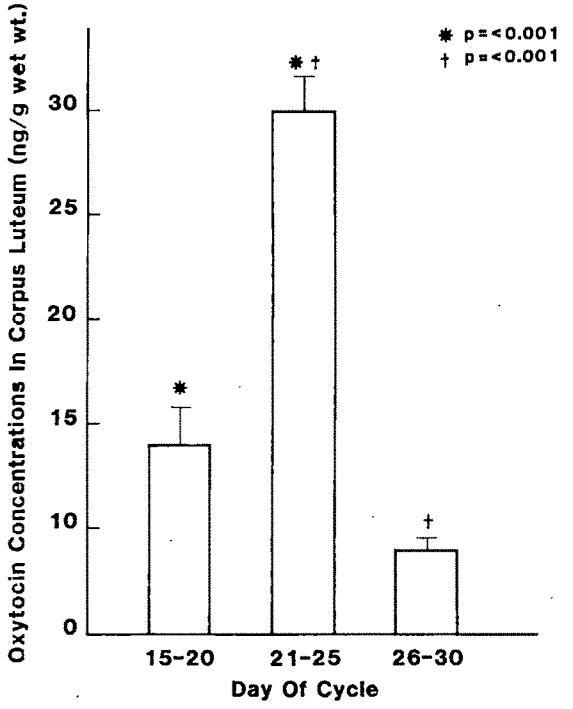

Fig. 3. Mean ± SE oxytocin concentrations in human corpus luteum during early (days 15 to 20), mid (21 to 25), and late (26 to 30) luteal phases. There was a significant increase in oxytocin concentration from the early to the midluteal phase (p = <0.001), followed by a significant decrease in the late luteal phase (p = <0.001).

column to remove impurities.[10] The eluates were collected, lyophilized, and resuspended in 1 ml of oxytocin radioimmunoassay (Tris–hydrochloric acid) buffer; an aliquot of this was taken for radioimmunoassay of oxytocin. Recovery of oxytocin from the ovarian tissue was determined by adding known quantities of iodine 125–labeled oxytocin to the minced tissue, which was then homogenized in 0.4 mol/L of acetic acid at 4° C and centrifuged at 800 × g for 20 minutes, and an aliquot of the supernatant was taken for determination of radioactivity. The mean ± SE (standard error of the mean) recovery of oxytocin for the extraction of oxytocin from the tissue was 91.9% ± 0.9%. All results of tissue concentrations of oxytocin were expressed without correction for recovery.

The acidified plasma was extracted for oxytocin with Fuller's earth as described by Dawood et al.[11] Immunoreactive oxytocin was determined by a specific and sensitive radioimmunoassay as described by Dawood et al.[11] with the use of ^{125}I-labeled oxytocin and a specific oxytocin antiserum raised in rabbits immunized against oxytocin conjugated to bovine serum albumin. The sensitivity of the assay was 1 pg per assay tube (1 μL of oxytocin = 2 pg) or 0.2 ng of oxytocin per gram of tissue, with intraassay and interassay coefficients of variation of 7% to 15% and 12% to 18% respectively. The cross-reaction of the oxytocin antiserum has been shown to be <0.8% with angiotensin and <0.2% with lysine-vasopressin, arginine vasopressin, vasotocin, luteinizing hormone releasing hormone, neurophysins I and II, and α-melanocyte-stimulating hormone. The final recovery of oxytocin in plasma with use of our method of extraction with fuller's earth was 42.5% ± 0.5%.[11] All results for plasma oxytocin were corrected for procedural losses.

Serial dilutions of the lyophilized, Sep-Pak–purified ovarian tissue extract in 0.05 mol/L of Tris-hydrochloric acid buffer containing 1% bovine serum albumin were subjected to radioimmunoassay of oxytocin to determine parallelism with the oxytocin standard curve. Reverse-phase high pressure liquid chromatography of the corpus luteum extracts was performed on a Waters binary automatic gradient controller (model 680), and the protein peaks were detected with use of a fixed wavelength ultraviolet detector (model 441). The samples were chromatographed at room temperature on a Bondapak C_{18} (3.9 mm × 30 cm) column with use of two different solvent systems, A (99.9% water and 0.1% trifluoroacetic acid) and B (70% acetonitrile, 29.9% water, and 0.1% trifluoroacetic acid). The gradient employed was 2 minutes of 35% B, 37 minutes of 60% B, and 65 minutes of 100% B.

Steroid hormone assay. To determine ovarian tissue concentrations of estrone, estradiol, and progesterone, a small sample of the tissue was finely minced, homogenized in Tris-glycerol buffer at 4° C as previously described,[12] and centrifuged at 800 × g for 20 minutes, and the supernatant was used for extracting the steroid hormone. The ovarian tissue extract and the plasma samples were individually extracted with double-distilled anhydrous diethyl ether. The ether extract was evaporated to dryness, resuspended in phosphate buffer, and chromatographed on Sephadex-LH_{20} to separate estrone and estradiol, and progesterone from 17α-hydroxyprogesterone.[13, 14] Estrone, estradiol, progesterone, and 17α-hydroxyprogesterone concentrations were determined by specific radioimmunoassays as previously described.[13, 14] The specific antibodies used were raised against estrone-6-oxime bovine serum albumin conjugate, estradiol-6-oxime bovine serum albumin conjugate, progesterone-11-oxime bovine serum albumin conjugate, and 17α-hydroxyprogesterone 7α-carboxyethyl thioether bovine serum albumin conjugate for estrone, estradiol, progesterone, and 17α-hydroxyprogesterone, respectively. All results were corrected for procedural losses.

Statistical analysis. Data were expressed as mean ± SE. Means were compared by the nonpaired Student's *t* test or a one-way analysis of variance with the use of a two-tailed p value. Paired samples of ovarian vein plasma and corpus luteum hormone concentrations

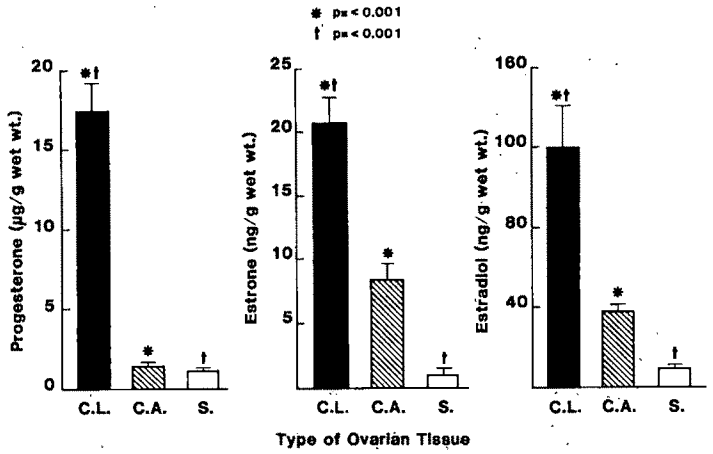

Fig. 4. Mean ± SE concentrations of progesterone, estrone, and estradiol in human corpora lutea *(C.L.)*, corpora albicantia *(C.A.)*, and ovarian stroma *(S)*. The concentrations of these steroids were significantly higher in corpora lutea than in corpora albicantia or ovarian stroma (p = <0.001).

were analyzed for correlation by means of linear regression; p values >0.05 were considered not significant.

Results

Serial dilutions of the corpus luteum extracts produced displacement curves parallel to that of oxytocin in the oxytocin radioimmunoassay. Reverse-phase hydrochloric acid of standard oxytocin (Sandoz) gave a single peak with a retention time of 14.06 minutes for oxytocin under our experimental conditions. A similar corresponding peak with a retention time of 14.06 minutes was also seen in the corpus luteum extract (Fig. 1).

The mean ± SE concentrations of oxytocin in corpora lutea (17.3 ± 2.8 ng/gm wet weight) was significantly higher than in corpora albicantia (1.6 ± 0.2 ng/gm wet weight; p = <0.01) (Fig. 2). Ovarian stroma had undetectable levels of oxytocin.

The concentrations of oxytocin in the corpus luteum increased significantly from the early luteal phase (days 15 to 20) (14.0 ± 1.8 ng/gm wet weight) to reach a maximum (30.8 ± 0.9 ng/gm wet weight) in the mid-luteal phase (days 21 to 25) followed by a significant decline to 8.0 ± 0.8 ng/gm wet weight in the late luteal phase (days 26 to 30; p = <0.001) (Fig. 3).

Fig. 4 shows the concentrations of progesterone, estrone, and estradiol in corpora lutea, corpora albicantia, and ovarian stroma. The mean ± SE concentrations of these hormones were as follows: (1) progesterone, 17.3 ± 1.8 µg/gm wet weight in corpora lutea, 1.4 ± 0.1 µg/g wet weight in corpora albicantia, 1.1 ± 0.1 µg/gm wet weight in stroma; (2) estrone, 20.8 ± 2.0 ng/gm wet weight in corpora lutea, 8.9 ± 0.8 ng/gm wet weight in corpora albicantia, 2.2 ± 0.9 ng/gm wet weight in stroma; and (3) estradiol, 120.5 ± 20.4 ng/gm wet weight in corpora lutea, 37.8 ± 3.9 ng/gm wet weight in corpora albicantia, 9.2 ± 0.9 ng/gm wet weight in stroma. For all three steroids, the corpora lutea had significantly higher concentrations than corpora albicantia or the stroma (p = <0.001). Corpora albicantia also had significantly more estrone and estradiol than the stroma (p = <0.001).

In the corpus luteum, oxytocin concentrations were significantly correlated with estrone (p = <0.025) and estradiol concentrations (p = < 0.005) but not progesterone concentrations (Fig. 5).

The mean ± SE plasma levels of oxytocin are shown in Fig. 6. The plasma levels of oxytocin in the ovarian vein draining a corpus luteum (n = 8) were significantly higher than in the ovarian vein without a corpus luteum during the follicular (n = 10) and luteal phases (n = 14) (p = <0.001) and in the peripheral blood during both the follicular and luteal phases (p = <0.001). There were neither significant differences between plasma oxytocin levels in the peripheral circulation (follicular phase, n = 13; luteal phase, n = 15) and in the ovarian vein without a corpus luteum (follicular phase, n = 10; luteal phase, n = 14) nor between the follicular and the luteal phases.

Fig. 7 shows that there was a significant correlation between corpus luteum concentrations of oxytocin and the ipsilateral ovarian venous plasma levels of oxytocin (r = 0.73, p = <0.05), estrone (r = 0.83, p = <0.025), progesterone (r = 0.96, p = 0.001), and 17α-hydroxyprogesterone (r = 0.77, p = <0.05). There was no significant correlation between corpus luteum oxytocin concentrations and ipsilateral ovarian vein levels of estradiol.

Comment

The present study reports the largest number of human corpora lutea and corpora albicantia ever determined for oxytocin, and for the first time, ovarian vein oxytocin levels are measured and their relationship to

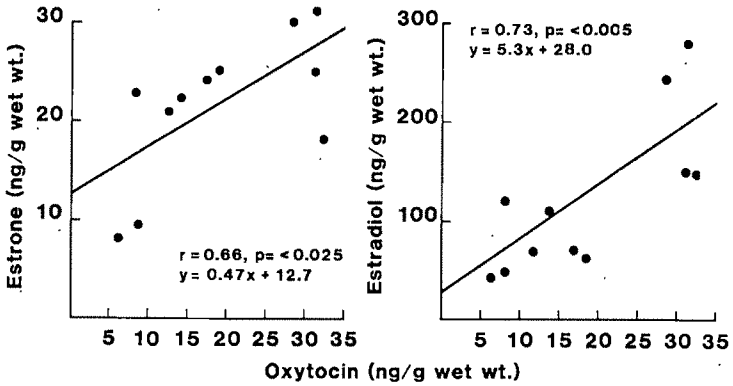

Fig. 5. Correlation between corpus luteum concentrations of oxytocin and estrone and estradiol. There was a significant correlation between oxytocin and estrone and between oxytocin and estradiol concentrations in the corpus luteum.

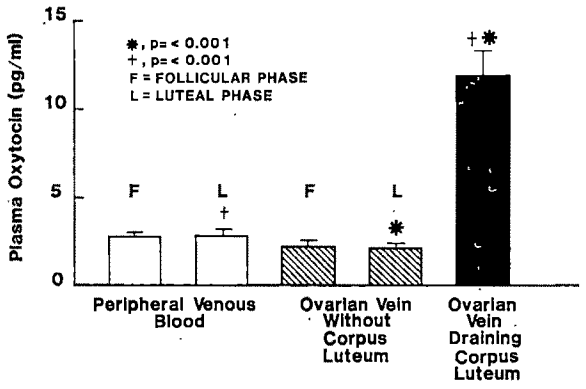

Fig. 6. Mean ± SE of ovarian and peripheral venous plasma oxytocin concentrations. The mean oxytocin concentration in ovarian venous plasma draining a corpus luteum was significantly higher than either ovarian venous plasma not draining a corpus luteum or peripheral venous plasma ($p = <0.001$).

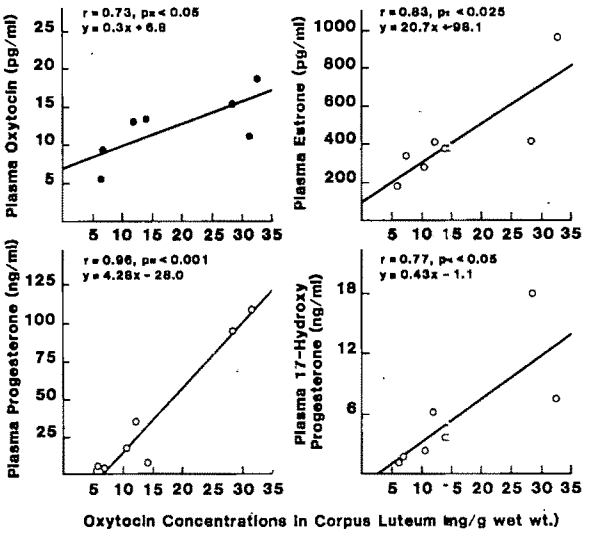

Fig. 7. Correlation between oxytocin concentrations in the corpus luteum and plasma oxytocin, estrone, progesterone, and 17α-hydroxyprogesterone levels in the ipsilateral ovarian vein. There was a significant correlation between corpus luteum concentration of oxytocin and ipsilateral ovarian venous plasma oxytocin, estrone, progesterone, and 17α-hydroxyprogesterone.

ovarian steroid examined. Our findings clearly show that immunoreactive oxytocin is present in human corpus luteum of the menstrual cycle. This peptide-like material is similar to the standard oxytocin as demonstrated by reverse-phase high pressure liquid chromatography (retention time = 14.06 minutes) and by our specific radioimmunoassay, thus confirming the initial observations in both systems.[3,4] The mean oxytocin concentrations of 17.3 ng/gm wet weight in human corpora lutea is similar to that reported earlier in a smaller number of corpora lutea both from our laboratory[4] and by Wathes et al.[3] but are much lower than the concentrations in the corpora lutea of monkeys,[6] cows,[2] or sheep.[2]

Oxytocin is present in the corpus luteum in significantly higher concentrations than in the corpus albicans, but ovarian stroma had undetectable amounts. This suggests that oxytocin is either produced or stored in the corpus luteum. In ruminants, bovine luteal cells and ovine large luteals cells[9] biosynthesize oxytocin in vitro from tritiated leucine. Because oxytocin concentrations in human corpus luteum increased significantly to a maximum level at midluteal phase (days 21 to 25) followed by a significant decline in late luteal phase (days 26 to 30) and a further reduction in the corpus albicans, the active corpus luteum appears to be the source of the oxytocin. This parallelism between the corpus luteum oxytocin concentrations and luteal function vis-à-vis progesterone secretion indicates a probable linkage between corpus luteum oxytocin and luteal steroidogenesis.

This is the first report of oxytocin levels in the ovarian vein which reflects ovarian secretion of oxytocin. In the absence of a corpus luteum the ovarian venous oxytocin

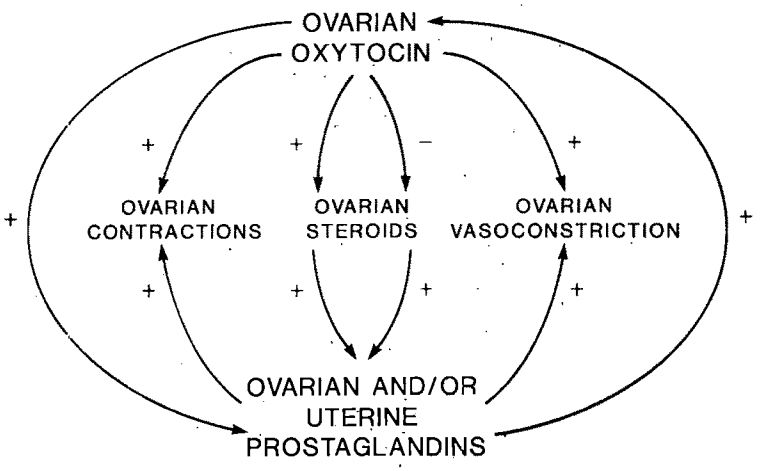

Fig. 8. Hypothesis for the role of oxytocin in human luteal function. The plus sign (+) indicates a stimulatory action while the minus sign (−) indicates an inhibitory effect.

levels are similar to peripheral circulating oxytocin levels, suggesting little or no output of oxytocin from the ovary. When a corpus luteum is present, the ovarian venous effluent has oxytocin levels five times higher than in the contralateral ovarian venous drainage or in the peripheral circulation. This further points to the corpus luteum as the source of oxytocin that is secreted into the ovarian circulation. In the sheep, ovarian venous blood draining the corpus luteum had higher oxytocin levels than jugular venous blood in response to the prostaglandin analog, indicating ovarian secretion of oxytocin.[15]

When corpus luteum oxytocin concentrations are compared to estrone, estradiol, and progesterone concentrations in the same corpus luteum, there is a significant correlation between oxytocin and estrone and estradiol, which suggests that intraluteal oxytocin may directly modulate production and/or secretion of luteal tissue estrone and estradiol levels. The highly significant positive correlation between intraluteal oxytocin concentrations and the ipsilateral venous plasma estrone, progesterone, and 17α-hydroxyprogesterone reflects an in vivo association between luteal tissue oxytocin and its effect on luteal release of its steroid hormones. These findings combined with the parallel rise and decline in corpus luteum oxytocin in mid and late luteal phase vis-à-vis luteal secretion of and circulating levels of progesterone strongly favor a regulatory role of ovarian oxytocin on luteal steroidogenesis and steroid hormone secretion. In this respect, oxytocin was found to be inhibitory on in vitro biosynthesis of progesterone by human corpus luteum cells, but the dose of oxytocin employed was very high.[7] In some nonprimate species,[2] several lines of investigation including oxytocin administration during the luteal phase as well as active and passive immunizations produced variable effects, some of which suggest that oxytocin is a luteolysin.[2] In subhuman primates, direct intraluteal administration of oxytocin shortened the luteal phase and decreased circulating levels.[16] No such direct evidence is available in women, but the results of the present study suggest that luteal tissue oxytocin regulates luteal tissue steroid levels and their release.

Although the precise mechanisms and effect of oxytocin on human luteal function have not been elucidated, we hypothesize that oxytocin may have a permissive luteotropic effect in low tissue concentrations (as in the early luteal phase) and a luteolytic effect (as in the midluteal phase, days 21 to 25) in high tissue concentrations. The luteolytic effect of oxytocin may be mediated through (1) a direct inhibition on luteal steroidogenesis, (2) stimulation of endometrial and/or ovarian prostaglandin, (3) ovarian vasoconstrictive effect, (4) ovarian contractility, or a combination of all these effects (Fig. 8). Further studies are necessary to define the role of oxytocin in human luteal function.

We thank Josie Ramos for excellent assistance in this study.

Discussion

DR. CHARLES B. HAMMOND, Durham, North Carolina. The authors are to be congratulated for an excellent paper that investigates human ovarian oxytocin, addresses its source, and attempts to begin to define its relationship to steroid hormone production from the ovary.

It has become increasingly apparent that control of the function of the corpus luteum involves very complex interactions and effects among glycoprotein, polypeptide, and steroid hormones. Luteotropic and luteolytic effects of luteinizing hormone, prolactin, estrogens, progesterone, gonadotropin-releasing hormone, and growth factors have been demonstrated in vivo and in vitro.[1] With the use of the classification system of Sporn and Todaro[2] there is evidence that these luteotropic and luteolytic effects may be achieved by endocrine, paracrine, and autocrine secretion. Unfortunately, a comprehensive description of such effects is hampered by species variability and menstrual cycle phase specificity.

The authors have presented convincing data which support the conclusion that oxytocin is present and is probably produced in the human corpus luteum. I congratulate the authors on their experimental design and their rigorous analytical techniques.

My only concern about this paper is that the authors have made a very significant, inductive leap from their analysis of their data to a model of corpus luteum function that does not seem warranted. Much of the discussion is an attempt to provide a relationship (directly or indirectly) of oxytocin to corpus luteum function. This does not seem feasible with the corre ative analyses used. Correlations do not establish cause The authors have little factual information to suggest that "luteal tissue oxytocin regulates luteal tissue steroid levels and their release." Although they have demonstrated an association between intraluteal oxytocin, estrone, estradiol, and progesterone concentrations, I do not think they have presented sufficient data to support an effect of oxytocin on modulation of luteal steroidogenesis and secretion.

I have several questions for the authors:

1. Oxytocin receptors have been identified in myometrium[3] and in smooth muscle cells of the fallopian tube.[4] Is there evidence that such specific oxytocin receptors exist in the cells of the corpus luteum?

2. What data exist to suggest that ovarian oxytocin secretion is modulated by gonadotropins or gonadal steroids?

3. There remains the issue of the re ationship between oxytocin and prostaglandins. This area clearly needs further study. Some questions to be answered are the following: Does oxytocin secretion result in changes in luteal prostaglandins? What are the comparative "luteolytic" effects of prostaglandin $F_{2\alpha}$ and oxytocin in vitro on human luteal cells? What are luteal concentrations of prostaglandin $F_{2\alpha}$ and oxytocin in the situation of early pregnancy, and do they change similarly or in different fashion? Could oxytocin and prostaglandins influence each other's production? Are both oxytocin and prostaglandins luteolytic, or is one acting via modulation of the other?

Again, I have enjoyed this paper and congratulate the authors. As so usually happens, good research often asks more questions than it answers.

DR. JOHN P. GUSDON, JR., Winston-Salem, North Carolina. I wonder if this might be a function of the presence of receptors for oxytocin in the corpus luteum?

My other question is, would it be possible, Dr. Dawood, to culture the corpus luteum and simply add a radioactive precursor aminoacid and see whether it is present in the subsequently isolated oxytocin?

DR. FRITZ K. BELLER, Munster, West Germany. In the present patient is there an oxytocinase present in

blood? Since there is an oxytocinase activity available in the blood, is there a local amino peptidase known to be an inhibitor of the corpus luteum?

DR. DAWOOD (Closing). In response to the questions by Dr. Hammond and Dr. Gusdon regarding whether oxytocin receptors are present in the corpus luteum, there are no published data on whether oxytocin receptor is present in human corpus luteum or in the corpus luteum of the cow or the sheep.

We are currently doing some collaborative work that will elucidate this.

In response to Dr. Gusdon's second question, which was whether cultured corpus luteum incubated with radioactive aminoacids will produce radioactively labeled oxytocin, we have carried out preliminary experiments on three corpora lutea obtained on days 21, 23, and 25 with use of radioactively labeled cysteine. Based on our preliminary results, we are able to show that there is bioconversion of radioactive cysteine and its incorporation into a peptide that is identical to oxytocin on reverse-phase high pressure liquid chromatography.

As a follow-up to Dr. Hammond's discussion, we can further show the presence of oxytocin in the human corpus luteum by immunocytochemical localization. We believe that this is the first demonstration of immunocytochemical evidence for oxytocin in the large luteal cells of the human corpus luteum other than previous demonstrations in bovine and ovine corpora lutea.[1, 2] In our laboratory we have just been able to demonstrate in a human corpus luteum of day 21 of the menstrual cycle, dense immunostaining of immunoreactive oxytocin in the luteal cells with a specific oxytocin antiserum by means of the peroxidase-antiperoxidase technique. The immunostained granules are mainly in the cytoplasm of the lutea cells.

Our lead to the role of oxytocin in steroidogenesis was stimulated by the fact that we have found the presence of oxytocin in many human tissues that produce steroids, namely, in the adult adrenal gland, in the fetal adrenal gland, in the testes, and in the ovaries of several species.

This has also been shown in other species by a number of laboratories in Europe. Thus there appears to be some association between steroidogenesis and oxytocin.

Whether oxytocin and steroids regulate one another, that is, oxytocin regulating steroids and steroids in turn regulating oxytocin, remains to be further clarified.

We agree with Dr. Hammond that association does not imply invariably a cause-and-effect relationship, but it implies some kind of a relationship that needs to be further elucidated.

However, based on in vitro studies on human corpora lutea,[3] it has been shown that with use of large doses of oxytocin, as much as 400 ng, secretion and production of progesterone can be significantly inhibited. Therefore there appears to be some direct evidence, at least in vitro, that oxytocin may play a role in the control of human corpus luteum. Our present study is an early attempt to show whether there is such a relationship in vivo.

Is there any effect of oxytocin on prostaglandin? Yes, we believe there is an effect of oxytocin on prostaglandin. This has been shown in many other models but not on the corpus luteum. Perhaps the same mechanism applies in the corpus luteum, but it remains to be shown by direct experimental evidence.

Is there a relationship between oxytocin and prostaglandin in the luteal cells?

Previous studies on measurement of prostaglandin in the luteal cells indicate that the luteal cells have a much lower concentration of prostaglandin $F_{2\alpha}$ than the ovarian stroma. Therefore a relationship may exist between ovarian stroma prostaglandin and luteal oxytocin which is consistent with and invokes the paracrine regulation of the corpus luteum.

Finally, is there a relationship between oxytocin and prostaglandin in the corpus luteum of early human pregnancy?

We have no information about this in early pregnancy but have examined five corpora lutea obtained at elective cesarean section at term, and the amount of oxytocin present in such corpora lutea is low. They are in the range of the oxytocin concentrations found in corpora albicantia. Thus it appears that the concentration and production of oxytocin in such corpora lutea during pregnancy is turned off or inhibited.

In response to Dr. Beller's question whether there is oxytocinase in the blood, yes, it is present in human blood even during the menstrual cycle.

Is there an inhibitor of oxytocin in the corpus luteum? I am not aware of any direct measurements or evidence showing the presence of such an inhibitor, if there is one.

Midforceps deliveries: Long-term outcome of infants

LeRoy J. Dierker, Jr., M.D., Mortimer G. Rosen, M.D., Karen Thompson, L.P.N., and Patricia Lynn, Ph.D.

Cleveland, Ohio, and New York, New York

Infants delivered by midforceps between 1976 and 1982 were evaluated for evidence of developmental delay or neurological deficit by chart review. The 110 infants who were followed for at least 2 years were compared to a matched group of infants delivered by cesarean section. The cesarean section group was matched for the immediate indication for delivery (dystocia or fetal distress), birth weight, gestational age, sex, and race. There was no significant difference in abnormal outcomes in the two groups. (Am J Obstet Gynecol 1986;154:764-8.)

Key words: Midforceps, infants

Today management of labor is largely directed toward minimizing fetal neurological morbidity and traumatic injury. Electronic fetal monitoring is routinely used in patients at risk for fetal distress and cesarean sections have replaced vaginal delivery as the more frequent birth route when a difficult delivery is anticipated. Potentially traumatic manipulations such as podalic versions have been abandoned. In most cases even the vaginal breech birth has been replaced by cesarean delivery.

The question of the use of midforceps as an acceptable obstetric procedure has been raised. For example, midforceps deliveries have been criticized by some as being potentially traumatic to the fetus[1] and associated with increased perinatal mortality,[2] cerebral palsy,[3] and lower intelligence quotient scores.[4] In contrast, these findings have not been confirmed in other studies.[5-7]

It is recognized that difficult forceps deliveries, particularly from higher stations or with midcavity rotations, may be traumatic to both mother and fetus and are more likely to be associated with abnormal neonatal outcomes when compared to patients with normal labors and spontaneous vaginal births. However, since midforceps births are almost always associated with other risks for morbidity, the impact of the confounding variables such as dystocia and fetal distress is not clear.

In a recent survey of obstetric teaching programs throughout the United States and Canada, all but one of the 73% of respondents stated that the use of midforceps was being taught and that midforceps use varied from <1% to >8%.[8] Thus there appears to be a need for continuing the evaluation of this obstetric technique with respect to morbidity and mortality.

This study represents an evaluation of major neurological morbidity in infants delivered by midforceps in a teaching hospital during a time when midforceps deliveries were generally discouraged. Our aim was to determine whether the use of the forceps resulted in an increase in neurological morbidity when compared to a matched group of patients delivered by cesarean section.

Methods

A retrospective, matched-pair analysis of births at Cleveland Metropolitan General Hospital was conducted on deliveries from July 1, 1976, through December 31, 1982. Data from the antepartum, intrapartum, and neonatal time periods were collected and entered into a database file during the pregnancy and postpartum period. Midforceps deliveries were defined traditionally; the vertex was engaged in the pelvis (station 0 or below) but not resting on the perineum. All forceps rotations from occiput transverse or occiput posterior positions were classified as midforceps deliveries. Labor graphs with timed intrapartum events were generated on each patient at the time of data entry. Patients with fetal deaths before onset of labor, multiple pregnancies, or major congenital anomalies were excluded from the study.

The midforceps procedure was confirmed by chart review. The labors of the midforceps patients and the comparison cesarean birth population were matched for dystocia. Dystocia was defined as protracted active phase, arrest in active phase, or arrest of descent. In addition, the fetal match was for fetal heart rate findings suggesting fetal distress (as derived from the records), birth weight within 200 gm, gestational age within 2 weeks, sex, and race. The maternal charts were reviewed to confirm the characteristics of the midfor-

Table I. Morbidity of midforceps group (n = 110)

Case No.	*Birth weight (gm)*	*Gestational age (wk)*	*Indication*	*Rotation*	*Age at follow-up (yr)*	*Morbidity**
1	3470	42	Dystocia	–	8	Meconium,* learning disability in speech therapy
2	2490	39	Dystocia	+	4	Group B streptococcus meningitis,* seizure disorder/abnormal electroencephalogram
3	3030	39	Fetal distress	–	2	Cephalohematoma,* neonatal seizures,* language delay
4	3280	39	Fetal distress	–	6	Cephalohematoma,* seizures at age 3, language and motor skills delay
5	4100	40	Fetal distress	+	Neonatal death at 24 hours	Anoxic encephalopathy with subarachnoid hemorrhage at autopsy*

*Asterisks indicate neonatal events.

Table II. Morbidity of cesarean group (n = 110)

Case No.	*Birth weight (gm)*	*Gestational age (wk)*	*Indication*	*Age at follow-up (yr)*	*Morbidity**
1	3110	35	Dystocia	3.4	Severe language delay, expressive skills, intelligence quotient of 58
2	2300	41	Fetal distress	Neonatal death at 14 days	Seizures,* small for gestational age,* subarachnoid hemorrhage*
3	2700	37	Fetal distress	7	Meconium,* moderate speech and language delay
4	4500	40	Dystocia	2.2	Severe speech delay
5	3100	38	Dystocia	2.2	Severe motor delay—not walking at 2 years
6	3120	42	Dystocia	4.2	Meconium,* speech and motor delays
7	2690	39	Fetal distress	2.1	Meconium,* severe language delay
8	2880	39	Dystocia	3.8	Meconium,* motor and mental delay, spastic quadraplegia, seizures at 1.5 yr, death at age 4

*Asterisks indicate neonatal events.

ceps deliveries and to determine the immediate indication for delivery. The infant charts were reviewed to determine whether there were any clinical indications of physical or neurological abnormalities. Mothers of infants who were not followed in the hospital clinics were contacted and interviewed, and their medical histories were reviewed with their managing pediatricians. By study definition all infants had a follow-up evaluation for a minimum of 2 years unless death occurred earlier. Abnormal neurological and developmental outcomes were compared between the two groups with use of the χ^2 statistic.

Results

Midforceps deliveries were performed in 176 deliveries for an incidence of 0.8% (176 of 21,414 births). During the same period primary cesareans were performed in 9.3% of patients. Of the 176 infants delivered with use of midforceps, 110 infant charts were located for follow-up with information for a minimum of 2 years. Nearly all patients were monitored with use of electronic fetal monitoring. Abnormal outcomes were noted in five cases with use of midforceps (5%), as shown in Table I. Abnormal outcomes were observed in eight cesarean section cases (7%) as shown in Table II. One neonatal death was noted in each group. There was an additional death at the age of 2 months from sudden infant death syndrome in the cesarean group. Within each group the primary indications for delivery were evenly divided between dystocia and fetal distress. There were no significant differences in the incidence of clinically apparent abnormal outcomes between infants delivered by midforceps and infants delivered by cesarean section in this study.

Comment

As noted earlier, obstetric practices have certainly changed, and these changes include a decrease in the use of midforceps. Today midforceps applications are probably performed at lower stations than in previous years. However, this fact is more difficult to confirm. As noted earlier, the use of midforceps is still being taught in nearly all training programs.[8] The debate over the use of midforceps centers around their potentially traumatic effects with lasting neurological or intellectual sequelae to the infant.

In the past Eastman et al.[3] and Fuldner[9] demonstrated an association between midforceps delivery and cerebral palsy. Others, however, did not find this association.[10] Friedman et al.,[4] reporting on data from the Collaborative Perinatal Project, documented lower intelligence quotient scores in infants following midfor-

ceps deliveries when compared with spontaneous deliveries matched for labor abnormality. These lower intelligence quotient scores were noted with both protractions and arrests of the active phase and second stages of labor irrespective of delivery route when compared with normal controls (that is, patients with no labor abnormalities and spontaneous vaginal delivery). No comment was made of the intelligence quotient scores in patients with similar labor abnormalities delivered by cesarean section. Other investigators,[11] even those analyzing data from the same Collaborative Perinatal Project,[12, 13] showed no evidence of lowered intelligence quotient scores in midforceps patients.

This study presents clinical follow-up data for at least 2 years on each patient delivered by midforceps compared to a similar group of patients matched for sex, age, weight, race, dystocia, and fetal distress but delivered by cesarean section. Cesarean birth patients were the group selected for comparison, since it was the only alternative for prompt delivery. Vacuum extraction was not performed during this study period. Our data do not indicate that infants born following use of midforceps fared differently than cesarean patients when clinical evidence of neurological deficit was the criterion and when the reason for choice of birth route was controlled.

In these patients neurological abnormalities included delays in language, delays in reaching developmental milestones, seizures, or mental retardation. One neonatal death was noted in each group. Both fetuses showed evidence of hypoxic injury and intrapartum fetal distress. The infant dying of sudden death infant death syndrome is also noted. No implication regarding a causal relationship is made.

A retrospective study such as this has several potential weaknesses. The clinical follow-up of the infants could not be standardized. Care was rendered in many settings and at different ages. Similarly, abnormal outcome measures were based on the clinical evaluations of many different observers. Intelligence quotients were not determined in many children. We anticipate in most circumstances that major neurological sequelae, with clinical impact on development and performance, would be evident clinically.

We cannot address the question of lower intelligence quotient scores in patients delivered by midforceps. However, we note that the control group in Friedman's study consisted of patients matched for dystocia rather than fetal distress, a condition commonly associated with midforceps deliveries. Similarly, comparison was not made with patients delivered by cesarean when matched for labor abnormality.

It would appear that major concern for abnormal outcome would relate to outcome measures of clinical significance including learning disabilities, speech delays, cerebral palsy, and spastic quadraplegia. These are conditions linked with handicap in normal function.

One cannot conclude from this study that midforceps are safe. The operative procedure was infrequently used (0.8%) and generally from the +2 station or lower. One might interpret this as selection of only the relatively "easy" midforceps candidates. This attitude may well have been a factor, since our staff members no longer feel comfortable performing midforceps deliveries and tend only to perform those that they anticipate can be accomplished without difficulty. It is entirely possible that, if midforceps were done more frequently, more difficult midforceps procedures would be performed with higher risk to the infant. With the reservations we have described, it does appear that selected midforceps deliveries may be performed with no greater risk of abnormal outcome than that associated with cesarean section.

We do not plan to encourage more frequent use of midforceps in our residents' education program nor do we advocate their use electively for "training" purposes. We request that a faculty member be present for midforceps deliveries when possible. When they are used cautiously, we do feel that midforceps deliveries have a place in modern obstetric care.

Finally, we are not advocating a return to difficult midforceps procedures. When the alternative to cesarean is midforceps delivery, the use of the forceps remains a judgment decision of the obstetrician at the bedside. In the absence of evidence of fetal stress, however, continued observation, as described by Cohen,[14] may be the wisest choice.

Discussion

DR. E. J. QUILLIGAN, Sacramento, California. The authors are to be congratulated for they wisely have chosen to compare patients delivered with use of midforceps with those delivered by cesarean section for similar indications (dystocia and fetal distress). This is the only study that I know of which is matched in this manner. They have further matched the patients delivered by forceps and cesarean section according to gestational age, birth weight, race, sex, and type of labor dystocia. The only important variable that they have failed to match is the socioeconomic grouping. This may have been an automatic match in their population and is most important when examining less severe neurological impairment. The single bias that cannot be matched for is whether those patients delivered by cesarean section would have been difficult forceps deliveries; had the easy forceps deliveries alone been delivered by cesarean section, the neurological damage would have been less. The only way to answer this question properly is with a prospective randomized study. This study provides a firm rationale for conducting such a prospective study.

The results of their study may gladden the hearts of those who would like to decrease the cesarean section rate and those who feel that residents can be trained to do midforceps deliveries safely. Will either objective be accomplished with use of the criteria they must have used for a midforceps delivery? The cesarean section rate could be reduced by 0.8%, which is not a huge decrease in light of the marked increase that has occurred during the last 20 years (from 7% to 20%). However, any decrease is important, and it is only by chipping away at the high cesarean section rate that it will be reduced.

The resident training question is more difficult to answer because the resident must learn two things: (1) the judgment as to which patient is properly delivered with use of midforceps and (2) the technique necessary to do a safe midforceps delivery. If my calculations are correct, the Cleveland Metropolitan Hospital Obstetrics Service has 27 to 29 midforceps deliveries per year. Since they have five residents per year, each resident would be responsible for five to six midforceps deliveries during their training. Is this enough? A quick look at the numbers would yield a "no" answer, but a different analysis might say "yes." I think this is an important question because it applies to other areas of obstetrics and gynecologic residency training in which small numbers of patients may be available, such as vaginal delivery of a breech and some surgical procedures such as vaginal hysterectomy. There is no magic number that will assure that a resident has proficiency in either clinical judgment or surgical technique. The staff must judge each resident on an individual basis, which leads to a question concerning Dr. Rosen's data. How frequently was a staff member present when the resident did a midforceps delivery? In a previous article[1] with use of the same subset of patients, 15% of the patients were delivered by the staff. Are these the only patients who had a staff member present at delivery? Assuming that a staff member is present at each procedure and is evaluating the residents, how can our review boards be certain that the evaluation is a proper one? One way is to look at mortality and morbidity, comparing trends in both at the same institution and comparing one institution against some norms of other institutions with similar patient populations. What I am saying is that perhaps our residency review committees should look at criteria other than the numbers of cases per resident to evaluate training.

Referring again to this article, I was surprised at the high incidence (5% to 7%) of severe neurological abnormalities at 2 years of age in these patients, particularly the group delivered for dystocia. With use of the previous article's total of 61 patients with fetal heart rate abnormalities and the assumption that the remaining 115 patients were delivered for dystocia, this would yield a 3% incidence of neurological abnormalities in this population, a figure 30 times higher than the generally quoted ratio of 1:1000 in all deliveries. The incidence of neurological abnormality when delivery was performed for fetal distress was 5:122 or 40:1000 deliveries. Again, a very high figure, assuming these were primarily fetal heart rate abnormalities found during the second stage of labor. Would Dr. Rosen comment on these aspects of their study?

Finally, I would like to congratulate the authors for the best retrospective study that I have seen on this subject.

DR. CHARLES A. WHITE, New Orleans, Louisiana. As I listened, three questions occurred to me.

One, I was expecting to hear some information about the Apgar scores of the infants, and wonder if you would comment.

Second, I noticed in your two groups that there appeared to be only one infant in each group with a birth weight in excess of 4 kg. Do you have a particular form of management, perhpas a more liberal attitude toward cesarean section, in those infants who are recognized during labor or before labor to be in a macrosomic weight range?

Third, as obstetricians we must be concerned not only about the antenatal and the intrapartum events but also about the neonatal events. If you continue this study,

or if you were to begin a new study design, would you see any advantage in routine study of cord blood information, particularly pH and blood gases, to help in prediction of outcome in these newborn infants?

Dr. Edgar L. Makowski, Denver, Colorado. Do you have any data on umbilical cord gas studies comparing the two groups? Such results are critical in a study like this.

Dr. A. Brian Little, Montreal, Quebec, Canada. I have two questions to ask. I have been impressed over the years by Mortimer Rosen's very conservative practice of obstetrics, and the obvious question which has already been alluded to is, how does his population, not only his population of patients but his population of faculty, influence these results in view of his strong control of the obstetrics that is practiced at his institution?

The reason I say this is because my colleagues, Robert Usher and Mark Boyd, have recently reviewed our midforceps results; in the presence of our increasing cesarean section rate over a long period of time, there has also been an increase in the midforceps rate, and these are all performed with a faculty member being present.

The second question I would like to ask relates again to my two colleagues who have brought up a concept that I immediately rejected called "failed forceps." I do not know what failed forceps are. I have never had a case, and I know my learned colleagues in this room have never had one.

However, there appears to be an incidence of failed forceps in our institution which is on the increase. I am not sure what it means. Do you?

As a corollary to that, we have an increased number of complications following cesarean sections late in labor. Do you have a similarly increased incidence of complications?

Dr. James A. Low, Kingston, Ontario, Canada. I would like to pose a question in that we are now at a point where we must have morbidity measures to meaningfully assess the implication of different obstetric events.

One of the problems identified in this study is measuring morbidity at 2, 4, 6, and 8 years of age. I would like to ask the general question: Would they agree that it is time that we standardize our outcome measures and the methods used and begin to work collaboratively with developmental psychologists and pediatric neurologists in regard to these measures of morbidity.

Dr. Dierker, (Closing). First, the socioeconomic status of the patients was not coded prospectively in the computer at the time. When we evaluated the relative incidence of private versus staff cases, we found that 15% of the midforceps patients were private and 20% of the cesarean section patients were private, which is not dissimilar but they were not matched.

Another question regarding the staff being present as noted in our first paper, the most senior person evident by review of the delivery note was mentioned as the deliverer, so if a faculty person was present in the room, we counted him as the senior person being present; based on these criteria, as best as we could determine from our first paper, they were fairly equally distributed between second, third, and fourth year residents and faculty.

Dr. Quilligan noted the neurological abnormalities that seemed to be a fairly high incidence noted in both dystocia and distress groups. I certainly agree that it is higher than the national average for normal deliveries. However, this is a select population, since 42% of them had dystocia and 42% of them also had fetal distress in both groups.

Regarding the selected population, the population of our hospital is about 80% staff and 20% private.

Regarding Dr. White's comments, the incidence of low Apgar scores was the same in the cesarean section group and in the midforceps group. We had a 1-minute Apgar depression of about 32% and 6% for the 5-minute Apgar score.

We did not have cord blood gas data on all the patients. We did have the indication of asphyxia noted in the neonatal record defined by acidosis and apparent depression, and they were the same, 14% in each group. They were not matched. It just happened that way.

Regarding the apparently few cases of large for gestational-age infants, when we reviewed our initial series of 176, we found that the incidence of large for gestational-age infants was no higher in our midforceps group than in our general population, a finding that was a surprise to me, but it was the same as the normal population.

Dr. Makowski wondered about the umbilical cord gas data, but we did not have umbilical cord gas studies. We did have scalp sampling on a number of patients, but as I mentioned, there was a 14% incidence of asphyxia clinically and documented by blood gas studies in the newborn infant at the time of admission to the neonatal intensive care unit.

Regarding Dr. Little's comments on failed forceps, we rely on our computer search to determine whether we had any failed forceps. I could only locate 10 in our review of that same time period, which leads me to believe that they are not being coded as frequently as they probably occur.

He also had a question about the population—how we keep the residents from choosing cesarean section.

I think that our general policy is to encourage vaginal delivery. We use fetal scalp sampling liberally with fetal monitoring in virtually all of our cases of dystocia and allow the patient to continue vaginally as long as she is making progress until vaginal delivery.

Regarding the comments by Dr. Low, I agree that standardized follow-up is essential if we are going to compare outcome measures. It is our sincere hope that we will have the opportunity and the economic support to follow these infants prospectively when they reach appropriate age with suitable testing in the future.

The relationship between antepartum fetal heart rate, intrapartum fetal heart rate, and fetal acid-base status

James A. Low, M.D., Michael J. McGrath, M.D., Sharon J. Marshall, R.T., Anneke Fischer-Fay, B.A., and E. Jane Karchmar, B.A.

Kingston, Ontario, Canada

The relationships between antepartum baseline fetal heart rate, baseline variability, accelerations, decelerations, and fetal movement and intrapartum fetal heart rate, fetal acid-base assessment at delivery, and Apgar scores 1 and 5 minutes after delivery were studied in 290 mature pregnancies. There was a significant relationship between antepartum and intrapartum baseline fetal heart rate and baseline variability. There was no relationship between antepartum and intrapartum accelerations or decelerations. There was no correlation between antepartum fetal heart rate or fetal movement and fetal acid-base status at delivery or Apgar scores 1 and 5 minutes after delivery. There was a trend for decreased accelerations and decreased fetal movements to be associated with a low Apgar score 1 minute after delivery. (AM J OBSTET GYNECOL 1986;154:769-76.)

Key words: Fetal heart rate, fetal hypoxia

Antepartum fetal heart rate monitoring has become a widely accepted method of surveillance of the fetus at risk for uteroplacental insufficiency.[1, 2] However, reports of the role of the nonstress test have highlighted a number of problems.

Standardization of the test and its interpretation have not been achieved. Many investigators recommend a fetal heart recording of at least 40 minutes with the expectation that a healthy fetus should demonstrate two to five accelerations of a minimum of 15 bpm and 15 seconds.[2] Studies of the fetal state in normal pregnancies have demonstrated that the interval between successive accelerations may be 37 minutes and the interval between fetal movements as long as 75 minutes.[3] This has led to the recommendation that the recording of fetal heart rates should be extended to 80 to 120 minutes before being classified as nonreactive. Fetal heart rate accelerations are the most frequently used indicator of fetal reactivity. However, some authors continue to include baseline fetal heart rate, baseline variability, and decelerations in the identification of the compromised fetus.[4-7] These observations have been used to provide a composite score or describe a "terminal" record.

Studies of the predictive value of the nonstress test have used differing measures of outcome including fetal growth retardation, fetal distress during labor, fetal acidosis at delivery, low Apgar score, and fetal and neonatal deaths, often without adjustment for the confounding effect of gestational age. Nevertheless, a number of general conclusions have emerged from these studies.

The nonstress test has been criticized because of the low positive predictive value of a nonreactive test. False positive nonreactive fetal stress tests are usually reported to be in excess of 50%.[5, 8] The number of false positives can be reduced by extending the duration of the nonstress test to 80 minutes[9] or increasing the criteria required to define a nonreactive test.[5] However, these adjustments will decrease the sensitivity of the test.

It is generally agreed that a reactive nonstress test has a good negative predictive value providing reassurance about fetal well-being and a low incidence of fetal death.[2, 6, 10, 11] The incidence of false negative reactive nonstress tests in relation to a number of mortality and morbidity outcome measures has varied from 1.5% to 7%.[5, 8, 9, 12] However, there is some concern. The majority of tests are reactive (>90%). Thus the low false negative percentage represents a significant number of cases. Prospective studies of the nonstress test have in general had few fetal deaths. Yet fetal deaths with a reactive nonstress test are reported in most studies,[10] and a number were noted in a multi-institutional study reported by Freeman et al.[1]

The aim of this test is to detect those pregnancies with uteroplacental insufficiency and prevent fetal death. This implies that antepartum fetal heart rate can predict fetal hypoxia, which in turn may lead to morbidity or death during the subsequent perinatal period.

Low-risk pregnancies	78

The objective of this study was to examine this question in high-risk and low-risk pregnancies at term. The antepartum fetal heart rate characteristics obtained within 24 hours of delivery were studied in regard to their association with intrapartum fetal heart rate, intrapartum fetal hypoxia with metabolic acidosis at delivery, and low Apgar scores 1 and 5 minutes after delivery.

Methods

The study population consisted of 290 obstetric patients with a mature fetus who were admitted to the hospital for induction of labor. Two hundred twelve obstetric patients were classified as having a high-risk pregnancy because they exhibited one or more of the maternal or obstetric antepartum risk factors outlined in Table I. The remaining 78 pregnancies were classified as low-risk pregnancies.

Complications of labor included meconium in the amniotic fluid (53 patients [18%]) and abnormal uterine action or cephalopelvic disproportion (34 patients [12%]). There were 234 vaginal deliveries and 53 cesarean sections.

A 40-minute recording of antepartum fetal heart rate and fetal movement was obtained within 18 hours of the induction of labor. After induction of labor, a continuous recording of intrapartum fetal heart rate was obtained in those patients managed in the intrapartum intensive care unit. An acid-base assessment of umbilical vein and artery blood and an Apgar score at 1 and 5 minutes were obtained at delivery.

Antepartum fetal heart rate was recorded with Hewlett-Packard external fetal monitor model No. 8040A (Hewlett-Packard Co., Palo Alto, California), the patient having refrained from smoking and nourishment for at least 1 hour before the test. Forty minutes of satisfactory recording was obtained by a research assistant while the mother recorded fetal activity. Each record was scored by two research assistants. Any discrepancies were reviewed with one author (J. A. L.). The fetal heart rate was scored according to the following criteria.

Table II. Composite score of fetal heart rate and fetal movement

	0	*1*	*2*
Baseline rate	>160	141-160	≤140
Baseline variability	≤5 (×2)	≤5 (×1)	≥6
Accelerations	0	1	≥1
Decelerations	>1	1	0
Movements	0	1	>1

Baseline fetal heart rate was the rate in the intervals between uterine contractions or episodes of marked fetal activity. Fetal heart rate was scored for the first and second 20 minutes and averaged. An abnormal finding was a fetal heart rate >140 bpm.

Baseline variability represents the fluctuations of the baseline fetal heart rate. Baseline variability for the two 20-minute periods was classified according to the amplitude of the fluctuations as normal (≥5 bpm) or decreased (≤5 bpm). An abnormal finding was decreased baseline variability for one or two 20-minute periods.

Fetal heart rate accelerations are short-term increases of fetal heart rate of at least 15 bpm above baseline. The number of accelerations in 40 minutes was noted. An abnormal finding was a record with less than two accelerations in 40 minutes.

Fetal heart rate decelerations are transitory declines of the fetal heart rate by at least 15 bpm below baseline. The number of decelerations in 40 minutes was noted. An abnormal finding was a record with one or more decelerations in 40 minutes.

Fetal movements were indicated on the record by an event marker operated by the mother. The number of fetal movements in the 40 minutes recorded was noted. An abnormal finding was a record with fewer than two fetal movements in 40 minutes.

A composite score of fetal heart rate and fetal movement was calculated according to the criteria in Table II.

The continuous recording of intrapartum fetal heart rate was obtained with a scalp electrode applied at the time of induction of labor in 115 patients. For this study, each 20-minute period of the first hour and the last 3 hours of the fetal heart rate record was scored by a research assistant without awareness of the clinical characteristics, antepartum fetal heart rate, or laboratory data.

Table IV. Correlations between observations of corresponding antepartum and intrapartum fetal heart rate; correlation for deceleration was between the number of antepartum decelerations and the percent of intrapartum decelerations

Antepartum fetal heart rate	*Intrapartum fetal heart rate*			
	First hour		*Last 3 hours*	
	R	*p*	*R*	*p*
Baseline rate	0.38	0.0001	0.31	0.001
Baseline variability	0.34	0.0002	0.26	0.01
Accelerations	0.11	NS	0.10	NS
Decelerations	0.08	NS	0.05	NS

The criteria for baseline fetal heart rate, baseline variability, and fetal heart rate accelerations and decelerations were similar to those used in the antepartum period. Fetal heart rate decelerations were classified as variable or variable late decelerations.

Variable decelerations vary markedly in shape from contraction to contraction. The departure and return of fetal heart rate is abrupt and the lag time is variable.

Variable late decelerations are characterized by an onset late in the contraction phase, and the maximum point of the deceleration occurs more than 20 seconds after the acme of the contraction.

Total decelerations are the sum of variable and variable late decelerations. Total decelerations were classified according to the percent of contractions associated with a deceleration as follows: moderate, 5% to 30% and marked, >30%.

Fetal blood gas and acid-base assessments were performed on umbilical vein and artery blood at delivery. Measurements of pH were made with a microelectrode pH meter (Astrup AME-1). Oxygen tension and carbon dioxide tension were measured with an IL-113 system. Buffer base was calculated from the Singer Hastings nomogram and corrected for the degree of oxygen unsaturation. Evidence of fetal hypoxia was based on the presence of a significant degree of metabolic acidosis in the umbilical artery (umbilical artery buffer base <34 mmol/L).

Apgar scores were obtained at 1 and 5 minutes by an independent observer using a stop watch.

Statistical analysis between antepartum fetal heart rate and intrapartum fetal heart rate and measures at delivery included Student *t* tests and χ^2 analysis. Correlation coefficients were established for each relationship.

Results

The means, SDs, range, and incidence of abnormal results for the antepartum fetal heart rate and fetal movement are presented in Table III. The incidence of abnormal results were: fetal tachycardia (>140 bpm), 25%; decreased baseline variability (≤5 bpm), 23%; accelerations (≤1), 6%; decelerations (≥1), 47%; and fetal movements (≤1), 7%. Abnormal composite scores were defined as either ≤7 (17%) or ≤5 (3%).

The significance of antepartum risk factors in relation to no risk factors, and after term in relation to term pregnancies, with respect to antepartum fetal heart rate and fetal movement was analyzed. Baseline fetal heart rate was slightly lower in high-risk in relation to low-risk pregnancies (136 versus 139 [$p < 0.01$]) and after term in relation to term pregnancies (135 versus

137 [$p < 0.04$]). Otherwise no significant differences were observed for baseline variability, accelerations, decelerations, or fetal movements.

Relationship between antepartum and intrapartum fetal heart rate. The correlations between the corresponding observations of antepartum and intrapartum fetal heart rate are presented in Table IV. There is a significant correlation between antepartum baseline rate and intrapartum baseline rate in the first and last 3 hours of labor. Similarly, there is a significant correlation between antepartum baseline variability and baseline variability in the first and last 3 hours of labor.

However, there is no correlation between the number of accelerations or decelerations in the antepartum record and the number of accelerations or the percent of decelerations during the first or the last 3 hours of labor.

Variable late or late decelerations were observed in five patients (4.0%) during the first hour of labor and in 27 patients (23%) during the last 3 hours of labor. There was no correlation between the number of decelerations in the antepartum record and the number of late decelerations during the first hour of labor (R 0.03) or the last 3 hours of labor (R 0.01).

The associations between observations of abnormal antepartum fetal heart rate and the corresponding intrapartum fetal heart rate are outlined in Table V.

Baseline tachycardia and decreased baseline variability in labor is more likely to occur in patients with baseline tachycardia and decreased baseline variability in the antepartum period.

There is no evidence that decreased antepartum accelerations are predictive of decreased accelerations during labor. Although there was no correlation between the number of antepartum decelerations and the percent of decelerations during labor, there is a trend for the patients with antepartum decelerations to have a greater incidence of patterns of marked deceleration. No association was found between antepartum baseline tachycardia, decreased variability, decreased accelerations or decelerations, and variable late or late decelerations during the first and last 3 hours of labor.

Relationship of antepartum fetal measures to outcome measures at delivery. The range of umbilical artery buffer base at delivery and the Apgar scores at 1 and 5 minutes are presented in Table VI. The significance of antepartum risk factors and duration of labor to the outcome measures was analyzed. There is a trend to a greater incidence of metabolic acidosis (umbilical artery buffer base <34) in high-risk in relation to low-risk pregnancies (12% versus 5% [$p < 0.07$]) and long labor (>7 hours) in relation to short labor (13% versus 6% [$p < 0.03$]).

The correlation coefficients between each antepar-

*$p < 0.05$.

tum fetal heart rate measure and the outcome measures are presented in Table VII. There are no significant correlations between antepartum fetal heart rate or fetal movements individually or as a composite score and umbilical artery buffer base at delivery or Apgar scores at 1 and 5 minutes.

The association between abnormal antepartum fetal heart rate and fetal movement and fetal metabolic acidosis and low Apgar scores at delivery is presented in Table VIII. There is no association between abnormal antepartum fetal heart rate or fetal movement and fetal metabolic acidosis. No consistent association was observed between abnormal antepartum fetal heart rate and fetal movement and low Apgar scores at 1 minute. However, there was a trend for decreased accelerations and decreased fetal movement to be associated with a low Apgar score at 1 minute.

An Apgar score less than 7 at 5 minutes was observed in seven newborn infants. There was no association between abnormal antepartum fetal heart rate and fetal movement and low Apgar scores at 5 minutes in this small number of newborns.

Comment

The low-risk patients with no major antepartum risk factors had the same incidence of abnormal antepartum fetal heart rate and fetal movement as the high-risk patients. This is in keeping with previous reports.[11] The incidence of less than two accelerations per 40 minutes was 6%. This closely parallels the frequency of nonreactive nonstress test reported in studies of high-risk pregnancies that have used this criterion alone.[1, 6, 8, 11]

The significant association between antepartum and intrapartum baseline rate and baseline variability suggests continuity of fetal state as expressed by these measures of fetal heart rate.

Intrapartum fetal heart rate, particularly patterns of total decelerations and variable late or late decelerations, are important predictors of intrapartum fetal hypoxia. There is no evidence that observations of antepartum fetal heart rate can predict either marked patterns of total decelerations or variable late or late decelerations during labor.

The best criterion of intrapartum fetal hypoxia is a fetal acid-base assessment with evidence of a significant metabolic acidosis. A number of reports of the significance of the nonreactive nonstress test have used umbilical vein or artery pH as one indicator of fetal distress or outcome morbidity.[4, 5, 9, 12] A recent study of elective sections has reported a trend to a higher incidence of umbilical vein pH <7.26 in infants with a nonreactive nonstress test before delivery.[13] No systematic study of the relationship of antepartum fetal heart rate and fetal acid-base status during labor has been reported.

In the present study, no correlation was observed

between antepartum fetal heart rate or fetal movement and umbilical artery buffer base at delivery. A significant metabolic acidosis (umbilical artery buffer base <34 mmol/L) was observed in 28 (10%) of the newborns at delivery. There was no association between observation of abnormal antepartum fetal heart rate or fetal movement and a significant metabolic acidosis at delivery. This implies that observations of abnormal fetal heart rate or decreased fetal movement cannot predict intrapartum fetal hypoxia within the next 24 hours. This was equally true in patients with a long labor (>7 hours) or a short labor (≤7 hours).

Apgar scores have been one of the outcome measures in a number of the studies of the nonstress test. The incidence of a low Apgar score at 1 minute (<7) has in general been greater after the nonreactive than the reactive nonstress test. The data from three reports[6, 7, 15] indicate that low Apgar scores are at least twice as common after a nonreactive nonstress test. Although there was no correlation between antepartum fetal heart rate or fetal movement and Apgar scores at 1 minute in the present study, there was a trend for decreased accelerations and decreased fetal movements to be associated with a greater incidence of low Apgar scores with a difference in incidence of the order of 2.

Most studies have placed greater emphasis on Apgar scores at 5 minutes as an indicator of fetal depression caused by hypoxia. The number of low Apgar scores at 5 minutes in most studies is usually less than 10. However, there was a trend to a greater incidence of low Apgar scores at 5 minutes in the multi-institutional study reported by Freeman et al.[1] There was no evidence of an association between antepartum fetal heart rate or fetal movement and the small number of low Apgar scores at 5 minutes in this study.

The stated aim of observations of antepartum fetal heart rate is to identify the initial manifestations of uteroplacental insufficiency, presumably expressed first by transient periods of mild or moderate hypoxemia with normal acid-base balance and subsequently by hypoxemia with metabolic acidosis. Studies in the fetal lamb and fetal monkey have provided valuable evidence of the fetal heart rate response to fetal hypoxemia. Baseline fetal heart rate tachycardia after an initial bradycardia has been demonstrated with moderate hypoxemia.[14] Hypoxemia with mild metabolic acidosis in fetal lambs resulted in no change in the number, amplitude, or duration of accelerations.[15] A decrease of accelerations is a late phenomenon associated with severe hypoxemia and acidosis.[16] Fetal heart rate decelerations occur when fetal oxygen tension falls below a critical level.[17] Decelerations in the fetal monkey occur with progressive hypoxemia before the development of metabolic acidosis.[16] There is an increase in the number and amplitude of decelerations in the fetal lamb with moderate hypoxemia with mild metabolic acidosis.[15]

These findings indicate that a moderate degree of hypoxemia is required to cause changes in fetal heart rate. Also baseline fetal heart rate tachycardia and appearance of decelerations rather than the disappearance of accelerations is the earlier sign of fetal compromise. Thus it is not surprising that observations of antepartum fetal heart rate cannot predict fetal hypoxia of uteroplacental insufficiency occurring 12 to 24 hours later with labor but rather reflects the state of the fetus at the time the observations were made.

Discussion

DR. ROBERT RESNIK, San Diego, California. For several years I have had the opportunity to learn from the careful clinical investigations carried out by Dr. Low and his colleagues from Kingston. His studies of the immediate neonatal, as well as long-term outcomes of growth-retarded infants, and those subjected to birth asphyxia in general have been significant contributions to our understanding of these pathophysiologic states.

Dr. Low has presented data that question the sensitivity of the nonstress test with respect to its ability to predict intrapartum fetal heart rate, baseline variability, and periodic changes, as well as neonatal outcomes reflected by acid-base status at delivery and Apgar score. His data do demonstrate that antepartum fetal heart rate monitoring will accurately predict intrapartum heart rate and variability in labors occurring within 24 hours of testing. However, he found no correlation with heart rate decelerations, acid-base status, or Apgar score. Indeed, among seven newborns with 5-minute scores of less than 7, neither antepartum fetal heart rate nor fetal movement activity was abnormal before labor. In short, the results support his conclusion that the nonstress test may not accurately predict fetal hypoxia in labors occurring within 24 hours of the test.

In all fairness, this may be too much to expect from the nonstress test. The loss of baseline variability and fetal accelerations with fetal movement are later rather than earlier signs of hypoxia. When the test is reactive, its proponents claim only that the fetus is well at that point in time and that 98% of fetuses will survive another week of pregnancy; they also concede a high false positive rate. However, Dr. Low's findings do focus our attention on the continuing debate regarding the relative merits of nonstress and contraction stress testing, as well as the biophysical profile, in their role as antepartum measures of fetal well-being. If one dispassionately evaluates the currently available data, it seems that all three tests are quite satisfactory, when properly selected and used with good clinical judgment. This statement is supported by the findings of Freeman et al.[1] in a multi-institutional assessment of the nonstress test and contraction stress test in high-risk pregnancies. They found the corrected perinatal mortality rate to be seven per 1000 among pregnancies followed with the nonstress test as the primary means of surveillance compared with three and a half per 1000 among those followed by the contraction stress test alone. Although some have concluded that these data show the contraction stress test to be a better predictor than the nonstress test by a factor of 2, it seems to me that a more appropriate conclusion is that both tests result in enviable perinatal mortality rates.

Nevertheless, studies in several animal models, as well as clinical observations, confirm that a late deceleration is an earlier sign of fetal hypoxia and that the loss of fetal heart rate variability and accelerations is a later consequence of ensuing acidosis. Following this line of reasoning, a contraction stress test would logically be an earlier and more sensitive indicator of hypoxia.

At the current time, there is considerable interest in tailoring the antepartum test to the specific fetal disease entity and combining these results with ultrasonic estimates of amnionic fluid volume. Data regarding predictive value of the biophysical profile are also quite promising, and it seems reasonable that eliciting a multitude of fetal responses is superior to observations of a single physiologic paramater. Parenthetically, I should point out that for two decades we obstetricians have searched for a single test that will tell us whether the fetus is healthy. This is unrealistic in as much as no such test exists for the more accessible adult organism.

Why did you use a 40-minute time limit for antepartum monitoring? When one considers the normal sleep and wake cycles of a fetus and their impact on variability, together with the observations of Brown and Patrick,[2] that the predictive accuracy of nonstress testing can be improved with an 80-minute observation, it seems likely that a longer test time would have improved the sensitivity. Second, it seems that a definition of a fetal heart rate greater than 140 bpm as abnormal is quite stringent. Would you explain your reasoning for these criteria?

DR. JOHN E. PATRICK, London, Ontario, Canada. I guess I probably reflect the feelings of most of us who have to go home and deliver high-risk pregnancies.

After hearing this presentation, I find myself asking, what should we as clinicians do? How do we use vital testing in our management of the high-risk pregnancy given your results?

DR. KEN NOLLER, Rochester, Minnesota. How did you select the women for inclusion in your study? Was this a group of normal women who were picked at random? Did they agree to the study?

I particularly wonder because since they had all been scheduled for induction, they could be women who were mostly at advanced gestational age, for example 42 or 43 weeks. The results then might not be predictive of women who were normal.

DR. HAROLD SCHULMAN, Mineola, New York. I wonder if this was a little bit of a statistical aberration. For example, if you had a larger series and a larger number of smaller for gestational age fetuses or those who had difficulty during labor and then selected that group and

saw what the predictability was, would we be seeing different results?

Dr. Low (Closing). The study population included patients admitted for induction of labor irrespective of the indication as long as they would consent to the protocol of the study. Two hundred twelve were classified as high risk and 78 as low risk based on selected antepartum risk criteria. Some of the low-risk patients then had intrapartum risk criteria.

This represents a population characteristic of many of the studies previously reported.

In respect to Dr. Schulman's question, we have looked at these associations in patients with long and short labors, in patients with and without antepartum risk factors, and in patients with and without intrapartum risk factors with the same results.

I agree with Dr. Resnik's comments. The need for a longer period of observation to use reactivity based on accelerations has been well demonstrated. The difficulty is the problem identified by Dr. Paul. There is a time implication if this test is to be used as a screening tool. As previous investigators, we selected 40 minutes as a compromise.

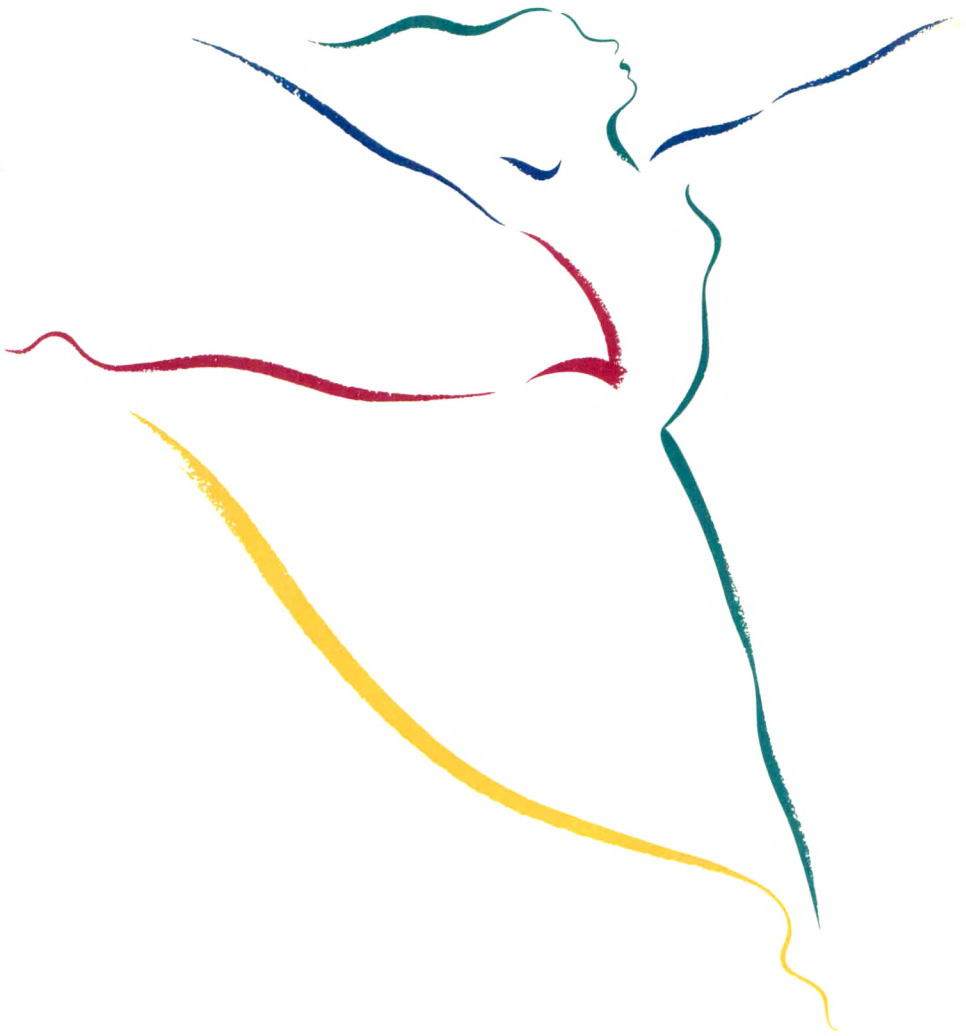
I would like to speak to Dr. Patrick's question. This is what really led us to this study. Any test that focuses our attention on the pregnancy at risk is positive. Most prospective studies of nonstress tests have low mortality rates. One of the variables is the degree of attention these patients receive.

Antepartum fetal heart rate is a noninvasive measure of the fetal state that will be useful in time. However, the nonstress test as it is presently interpreted is in my judgment, and I am sure some will not agree, a disservice to current clinical practice.

I believe that the statement "a reactive nonstress test provides reassurance about fetal well-being" should be discarded. All prospective studies of nonstress tests include unexpected fetal deaths, occurring within 24 hours of the nonstress test. Any busy obstetrician can provide anecdotal experiences of a fetus that has died within 24 hours of what they have observed to be a reactive nonstress test.

I agree with Dr. Resnik that it is time that we use tests for specific diagnoses. It is too much to ask of a single test that it identify all the fetal problems that may lead to morbidity or death. Where we have had a specific test for a specific diagnosis (Rh isoimmunization is one of the best examples), the results have been excellent.

Antepartum fetal heart rate should be interpreted in a way that will give it greater credibility, in spite of the fact that we lose sensitivity by so doing. There are several options in regard to the diagnosis of fetal hypoxia in the mature fetus.



The first is to extend the period of observation from 80 to 120 minutes. The nonreactive test at this point will be associated with a low false positive rate.

The second is to use the composite score within a 20- or 40-minute period. There are several points that support this approach. One of the problems is the interobserver variability in regard to the observations used in the nonstress test.

Our interobserver reliability ranged from 0.5 to 0.9, being low for baseline variability and decelerations. If we use a test that requires more stringent interpretation, we will get a better analysis of the record. Second, the animal studies emphasize that for the specific diagnosis of hypoxia, decelerations are probably more useful. Finally, Kierse and Trimbos (see reference 5) have demonstrated a low false positive rate with composite scores of 5 or less. If we wish to have a more creditable test, we need to use more stringent criteria and accept the decreased sensitivity of the test at the present time.

The final option, of course, is to pursue the investigation of the fetal state to find a measure that is more sensitive for this specific diagnosis.

New imidazole for vulvovaginal candidiasis

Introducing

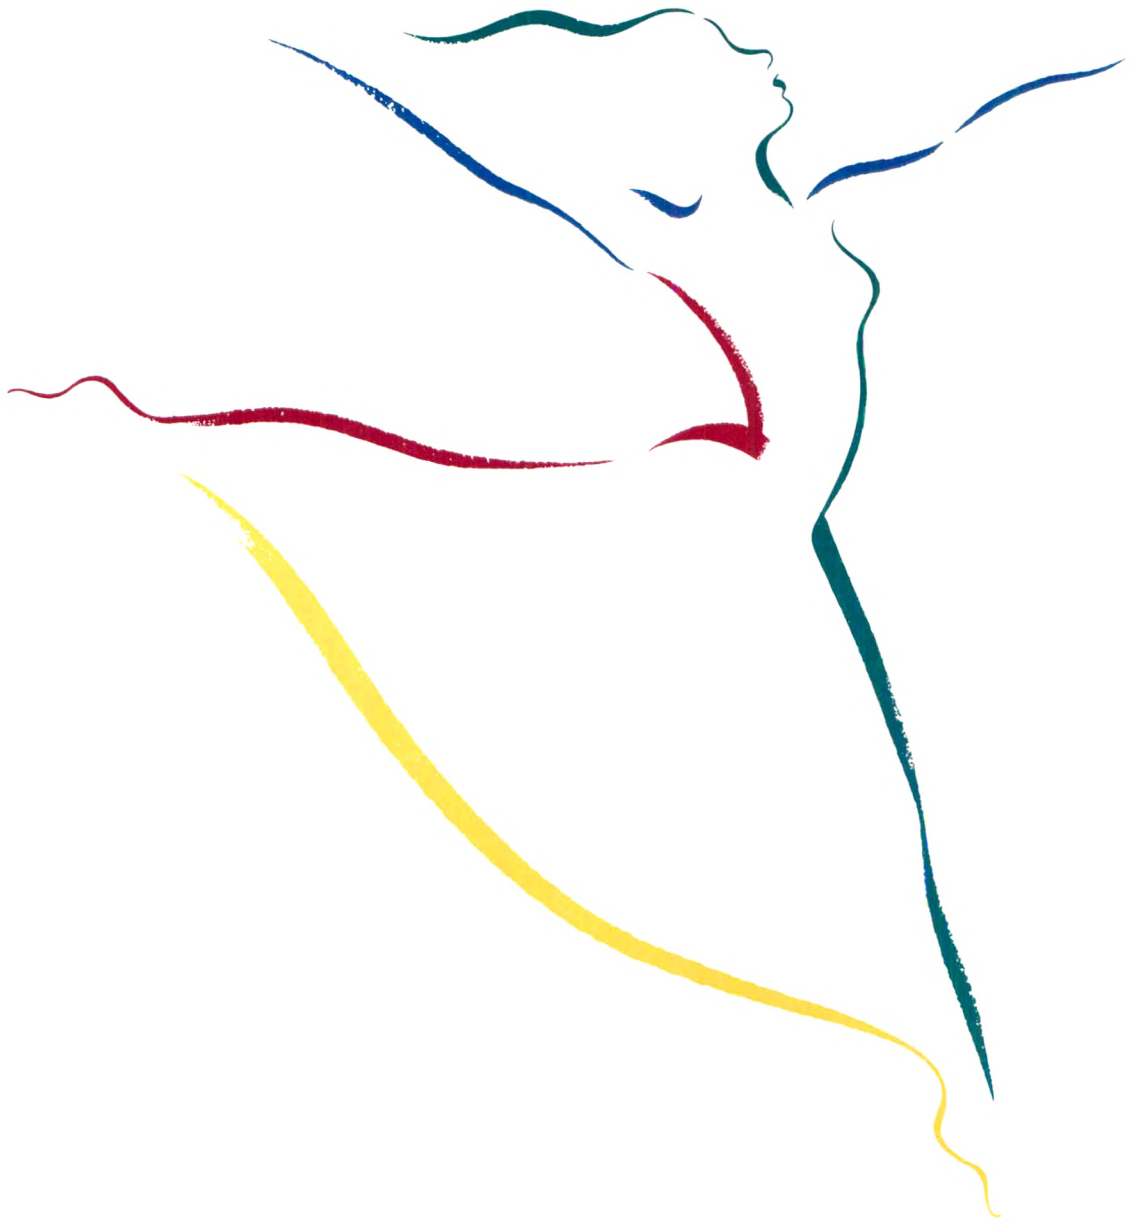
vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream*

*In non-pregnant patients, 3-day treatment is recommended. Treatment may be extended an additional 3 days, if necessary.



Please see brief summary of full prescribing information on last page.

SYNTEX

New imidazole for
vulvovaginal candidiasis

3-Day Cream

The shortest course of the preferred form[1]

New Femstat® vaginal cream 2.0%

(butoconazole nitrate)

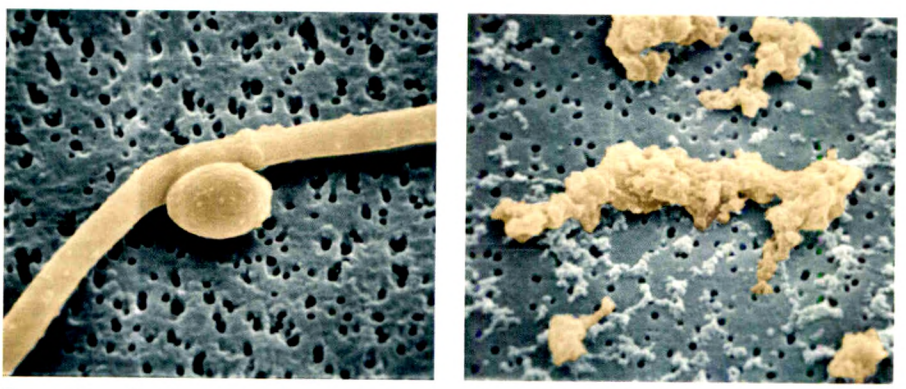
The Only 3-Day Cream

- Symptom resolution comparable to 7-day miconazole cream with only 3 days of therapy.[2]
- Cream—the preferred form for prompt relief of vulvar itching and burning.[1]
- Low recurrence rate at one-month follow-up.
- Minimal incidence of side effects—limited to local irritation.
- Exclusive disposable applicators to enhance patient compliance.

1. According to a 12-month nationwide industry audit (ending October 1985), comprised of approximately 2,000 pharmacies. Vulvar burning occurred in 2.3% and itching in 0.9% of patients on Femstat.
2. Bradbeer CS, Mayhew SR, Barlow D: Butoconazole and miconazole in treating vaginal candidiasis. *Genitourinary Med* 61:270-272, 1985. (Study conducted in non-pregnant patients.)

Please see brief summary of full prescribing information on the following page.

SYNTEX
SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304



New imidazole for vulvovaginal candidiasis

New Femstat®

vaginal cream 2.0%

(butoconazole nitrate)

The Only 3-Day Cream

Scanning electron photomicrographs (5000X) of *Candida albicans* grown for 48 hours in serum (left), and in serum with 200 mcg/ml butoconazole nitrate (right).

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Symposium on the need for flexibility in academic obstetric-gynecologic residencies

Flexibility in obstetric-gynecologic residencies: Why is it necessary?

Introduction

J. Robert Willson, M.D.
Albuquerque, New Mexico

In his presidential address before this Society in 1983 Dr. Edgar L. Makowski identified several major problems that confront teachers, investigators, and clinicians in our discipline. These included resident education, the number and qualifications of clinical-scientists, the need to make the public more familiar with our mission and more involved in supporting it, and finally, the care of the elderly and the poor. He appointed a committee consisting of Drs. Saul B. Gusberg, James M. Ingram, Richard F. Mattingly, George W. Mitchell, Jr., and Henry A. Thiede, with Dr. J. Robert Willson as chairman, and charged them to ". . . seriously examine and deliberate the issues and . . . to formally convey its recommendations to Council . . . for subsequent action."

Several of the issues are of particular concern to the American Gynecological and Obstetrical Society because it occupies a unique position among the societies in our discipline. It is the only one in which the basic responsibilities of the majority of Fellows are the teaching of medical students, the preparation of residents for practice, the development of academicians, and the administration and operation of personal and departmental research programs. Other of the problems mentioned by Dr. Makowski, for example, the care of the elderly and the poor, although important, require more resources for their study and solution than can be made available through the American Gynecological and Obstetrical Society. We chose therefore to concentrate on issues that were particularly pertinent to our endeavors.

The committee members recommended that the most suitable projects for the American Gynecological and Obstetrical Society to consider were the development of objectives for resident education in university programs and of methods for monitoring the progress of house officers toward meeting the objectives; the development of standards for preparation of residents, Fellows, and faculty members for academic careers; and the identification and recruitment of lay persons who could interface with governmental bodies, agencies, foundations, and institutions in behalf of university departments. In addition we suggested that we offer to assist the Residency Review Committee and The American Board of Obstetrics and Gynecology in developing guidelines for approval of more than one kind of resident experience in selected university programs and that we offer to assist other organizations, such as the Council on Resident Education in Obstetrics and Gynecology, in developing criteria for the appointment of a program director. Finally, we recommended that the American Gynecological and Obstetrical Society develop a forum in which those involved with university programs could discuss the issues raised by Dr. Makowski and consider methods for solving them.

Dr. Joseph Seitchik, who followed Dr. Makowski as President, directed a second committee, made up of Drs. Jack N. Blechner, Philip DiSaia, William Droegemueller, and Charles B. Hammond, with Dr. J. Robert Willson as chairman, to review the original report and to recommend action that would be appropriate for the Society to initiate.

We concurred with the observation of the first committee that it is much more difficult now than it was in the past to develop and maintain the highest quality resident education programs and to recruit and train academic faculty. The principal problems are that there is no general agreement as to how training in a university department should differ from that in a community hospital, that there is no effective way to evaluate the progress of house officers as they advance from year to year, that it is difficult to vary the length or content of standard residency programs to accommodate special individual needs, that financing for programs designed to prepare residents and Fellows for academic careers is less readily available, and that it is difficult to support young faculty members as they establish their own research programs. It also was obvious to us that requirements for appointment as program director, even in university residencies, are much too permissive.

We recommended the following: (1) that the President appoint a Committee on Graduate Education to study and evaluate the reports of the two Committees

From the Department of Obstetrics and Gynecology, The University of New Mexico School of Medicine.
Presented at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.
Reprint requests: J. Robert Willson, M.D., Department of Obstetrics and Gynecology, The University of New Mexico School of Medicine, Albuquerque, NM 87131.

and to recommend action steps that might be appropriate for the Society; (2) that a morning session during each annual meeting be devoted to discussion of a specific topic that concerns academic departments; (3) that the members of the Committee on Graduate Education and of the Program Committee cooperate in selecting the issue to be considered and in developing the program; and (4) that knowledgeable individuals, not necessarily Fellows of the American Gynecological and Obstetrical Society, be invited to prepare position papers to be presented and discussed during the session and that the papers and discussions be considered for publication with the scientific papers.

We also recommended that the first such session be developed for the 1985 meeting and that the subject be "Flexibility in obstetric-gynecologic residencies: why is it necessary?" Obviously, the Council approved the suggestion.

Finally, I should like to thank the members of both Committees who worked so diligently and effectively in gathering information on the issues and for their assistance in preparing the final reports. I also thank Drs. Jaffe and Hendricks for agreeing to prepare and present the papers today and to Drs. Merrill and Pitkin for their responses. They obviously share the concerns of the committee members.

The need for flexibility in preparing clinician-scientists for academic careers

Robert B. Jaffe, M.D.

San Francisco, California

Academic obstetrics and gynecology is not realizing its potential.

With reproductive sciences at the cutting edge of contemporary biology, and with increased numbers of outstanding, highly motivated and well-educated physicians choosing careers in obstetrics and gynecology, the discipline is not attracting a commensurate increase in the numbers of these highly qualified individuals into the academic research component of the specialty. The reasons for this are many and varied. They include: (1) lack of sufficient, appropriate role models during house officer training; (2) a negative perception of the competitive and political aspects of academic medicine; (3) the discrepancy in income between academic medicine and private practice; (4) inadequate exposure to, and hence inadequate appreciation of, the intellectual excitement of academic investigative pursuits; and (5) inflexibility in the training programs in obstetrics and gynecology in most academic centers. It is these latter two interrelated factors that will be the focus of much of this discussion. Although the majority of comments will be directed toward residency training, the discussion will be extended briefly to a consideration of the need for flexibility in fellowship training as well.

In many of the constituent disciplines of reproductive medicine and biology, reproductive science is, or should be, at the forefront. For example, in the field of endocrinology, over half of the articles in the two leading American endocrinologic journals deal with some facet of reproductive endocrinology. In the field of oncology, in which studies concerning normal and abnormal cell and tissue growth, oncogenes, and other aspects of cell biology have captured the imagination of fundamental biologists, gynecologic oncology has the opportunity to make meaningful strides. To a great degree, this potential has not as yet been realized.

There are no academic obstetrician-gynecologists currently in the National Academy of Sciences, only three in the Institute of Medicine, and just two in the Association of American Physicians, and tellingly, none are members of the American Society for Clinical Investigation, the "Young Turks," who are under 45.

In part because of (1) the excitement of contemporary reproductive biology, (2) a concern with important social issues, and (3) the attraction of being involved with both medical and surgical aspects of a discipline, as well as for a variety of other reasons, obstetrics and gynecology programs are attracting some of the brightest and best graduates of leading medical schools. Many of these individuals have had extensive research experience before beginning their house officer training. Yet relatively few pursue meaningful, academic investigative careers following their training. Of individuals who started Board-approved subspecialty fellowships that could have been completed before 1984, approximately 60% have full-time academic appointments. However, the number competing successfully for National Institutes of Health grants is very low compared to other academic disciplines. For example, in fiscal years 1983 and 1984, approximately 10% of National Institute of Child Health and Human Development extramural funding went to Departments of Obstetrics and Gynecology. Approximately half of the awardees held M.D. or M.D. and Ph.D. degrees. Thus about 5% of the awards of the National Institute of Child Health and Human Development and only 6% of its funds went to obstetrician-gynecologists. Of the total National

From the Department of Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco.

Presented at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.

Reprint requests: Robert B. Jaffe, M.D., Department of Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco, San Francisco, CA 94143.

Institutes of Health extramural budget, only 0.8% went to obstetrician-gynecologists.

Although various forms of scholarship are essential, it seems clear that there needs to be greater emphasis on productive research as an integral part of a greater number of academic departments of obstetrics and gynecology.

Several barriers exist for the pursuit of such research training. They include lack of significant exposure to contemporary research for the 4 years of residency training in many programs; a lack of first-hand experience in research by many of the leaders in obstetrics and gynecology; the presence of role models during residency training who spend most of their time in the clinical practice of obstetrics and gynecology; the additional time that would be required to satisfy subspecialty board requirements; and, for the individual with a strong research background, the 4-year period during which it is extremely difficult to keep current in and excited by contemporary investigative biology.

For these reasons we proposed several years ago an alternate residency training program for selected individuals who were contemplating academic careers and who had significant previous research experience. This program, in which at least two individuals would have to be contemporaneously enrolled for logistic purposes, would intertwine clinical training and research during a 6-year period. It would involve primarily clinical residency training during the first 2 to 3 years following medical school. Thereafter, a year would be spent in the laboratory and, in the case of reproductive endocrinology, in gaining expertise in the clinical aspects of endocrinology and infertility. After this the individual would complete his or her clinical and research training in a manner sufficient to qualify both for the general boards in obstetrics and gynecology and, for those areas in which subspecialty boards are offered, in those subspecialty areas as well. Although there is a limited number of centers in which such a program could be established now, this number can and should be expanded if the model is successful.

In my view the advantages of such a program are several: (1) the individual could stay in closer contact with the scientific aspects of the discipline without having to wait 4 years to renew that contact; (2) he or she would be guaranteed funding in advance for the fellowship experience as well as the residency; (3) research projects could be begun which could be continued during the remainder of the individual's training period; (4), and perhaps most important, the individual would have continued stimulus to pursue an investigative academic career.

The disadvantages to such a program include the following: (1) difficulties in scheduling rotations that would integrate these individuals with residents pursuing traditional 4-year training programs; (2) loss of some continuity in clinical training and experience; (3) decrease in the development of the camaraderie that occurs as an individual goes through training with the same group of individuals; and (4), unless these are additional positions rather than just substitute positions, antagonism and jealousies by other house officers. Although these disadvantages are real, in my view the advantages markedly outweigh the disadvantages.

However, the parent American Board of Obstetrics and Gynecology has not seen fit to give approval to such a program other than on a case-by-case basis. This is not feasible, since an applicant needs to know in advance, before making a decision about the location of his or her training program, that such an option would be available. In addition, program directors have to make decisions in advance so that they can plan appropriately for their training programs. It would seem that just as programs are approved for specialty and subspecialty training, selected programs also could be approved for this alternative form of training.

Two examples might be illustrative. Our house officer training program has had two individuals in it, both of whom had similar backgrounds and both of whom showed excellent promise for academic careers. Both had pursued M.D.-Ph.D. programs in medical school and had obtained their Ph.D. degrees in one of the foremost molecular endocrinology laboratories in the country. The first of these individuals, who completed his training 3 years ago, went through the conventional residency training program. He performed extremely well and, for several reasons, entered private practice at the conclusion of his training. His mentor in the laboratory in which he obtained his doctorate said that he was one of the most promising graduate students he had ever trained. While he is performing in an excellent fashion in clinical practice, there is a high likelihood that he also would have had a brilliant career in academic obstetrics and gynecology. The second individual, with a similar background, is the first to be pursuing the modified program which I described previously. On completion of his fellowship training, he will enter a faculty position in which, I predict, he will have a very productive career. Although there is no assurance that the first individual would have elected an academic career were he to have enrolled in the alternative pathway, it is my view that this would have enhanced the chances of his doing so.

Since there is a great need for exciting, well-trained clinician-investigators in academic departments of obstetrics and gynecology throughout the country, and since traditional training programs do not appear to be meeting this need, this alternative track seems worthy of trial in selected institutions.

With regard to fellowship training, it appears that

greater flexibility also might be beneficial if individuals are to be prepared for productive, academic research careers. Many of the current obstetric-gynecologic leaders in reproductive research pursued training programs that would be proscribed by current guidelines of the subspecialty boards. Thus, while many spent 1 or 2 years in a laboratory either abroad or in a basic science department in the United States, these are not components of "approved" programs of the current subspecialty disciplines. Furthermore, extensive clinical requirements, for example, the need for reproductive endocrinologists to train in tubal microsurgery and in vitro fertilization, and the large amounts of time in clinical pursuits mandated in fetal and maternal medicine and oncology mitigate against obtaining the requisite training to pursue an independent, productive, and competitive research-oriented career—and the discipline sorely needs this facet of the specialty better represented.

Although I was not personally involved, the activity of this Society of which I have been most supportive and proud has been the creation of the Kennedy-Dannreuther fellowships. They furnish tangible evidence of the Society's commitment to training investigators in the reproductive sciences. To maximize these opportunities, the greatest possible program flexibility needs to be encouraged and facilitated.

Experience with flexibility in an academic residency program

Charles H. Hendricks, M.D.
Chapel Hill, North Carolina

During my tenure as Director of the Residency Program in Obstetrics and Gynecology at the University of North Carolina at Chapel Hill, from 1968 through 1980, seven principles served as guidelines. All of these principles are important, but the first two were absolutely critical in our residency management during those years:

1. The residency exists primarily to serve the developmental needs of the resident and not the service needs of the hospital where he is being trained.

From the Department of Obstetrics and Gynecology, University of North Carolina School of Medicine.
Presented at the Fourth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 4-7, 1985.
Reprint requests: Charles H. Hendricks, M.D., Department of Obstetrics and Gynecology, University of North Carolina School of Medicine, 214 MacNider Building 202H, Chapel Hill, NC 27514.

2. Education is not neatly confined within the white picket fence of any institution nor tidily contained within a classical school year. The University should be thought of as a universal idea rather than as an institution. The strategy of utilizing the University should allow for rearranging the boundaries of time and geography where such adaptations can aid in the development of a single individual's career.

3. A residency should be considered to be a vital, demanding, prolonged postgraduate academic experience. Treating a residency training program as a trade school program demeans both the resident and the residency.

4. Ideally, residency experiences should be designed to help the person reach toward his highest aspirations for his own development. It is unrealistic to design a residency program to produce only academicians or only practitioners. Having high aspirations for a full-time academic career is no more worthy than having high aspirations for a successful career in private practice.

5. The individualization of resident care is just as important as the individualization of patient care.

6. Both the resident and the residency benefit by having some input by the resident, in the design of his own learning program.

7. It is manifestly impossible for the resident to "learn" obstetrics and gynecology during a 4-year period. Rather than "learning" the field, the resident should be learning intellectual inquiry and disciplined study methods that will qualify him as a life-long student in his chosen field. Only in this way can he hope to avoid boredom, obsolescence, and professional decay.

Strategies

The residents were selected through the usual selection mechanisms except for those who joined the program at an irregular time. We made provision for accepting as early starters, and therefore early finishers, those individuals who had completed their medical school requirements for the M.D. degree sooner than their fellows had done. During 12 of the years under study here, the resident applicants were encouraged to have some input into their own curriculum, designed to advance their personal goals. Their elective programs were determined partly by their requests and partly by suggestions offered by the faculty.

There was no requirement that any resident would have to perform any research. We did take care, however, to provide opportunities for research, which we enthusiastically aided and abetted.

If one applies seriously and logically all of the precepts listed above, it is perfectly apparent that there

Table I. Graduates of the University of North Carolina residency program by years, 1970-1982*

Year	*No. of graduates*
1970	4
1971	3
1972	2
1973	2
1974	4
1975	5
1976	5
1977	5
1978	3
1979	6
1980	4
1981	5
1982	5

*Mean number of graduates per year, 1970-1974: 3.0. Mean number of graduates per year, 1975-1982: 4.8.

will not necessarily be the same number of residents within the home hospital training department at any one time. There will be a great deal of coming and going of residents as they go from one assignment or elective to another in pursuit of the individual 4-year plan. Our training program needed to make allowances for the fact that the training was not even necessarily continuous. For example, when two of our residents dropped out after 2 years to work at the Centers for Disease Control, they returned to finish their final 2 years at the University of North Carolina. Three others joined the program at the second-year level.

The total number of graduates did not vary widely from year to year, since some residents transferred quite early to other activities. Altogether, 65 physicians entered the training program. Of these, 11 (17%) departed for other activities; only one of these was with our program more than a single year. Two entered required military service; after completing the military requirement, one of these went into family medicine, while the other completed the obstetrics and gynecology residency in another program. After no more than 1 year in our program, one resident left for further training in each of the following specialties: pathology, psychiatry, radiology, radiation therapy, ophthalmology, anesthesiology, pediatrics, and family practice. One resident departed after 2 years to enter the Public Health School.

The planned number of residents during most of the years was five per year (Table I). Actually, with one exception, in only one year was that number exceeded: in that year, there were six graduates. It should be noted, however, that in the year just preceding and the year just following that year, the actual number of graduates were only three and four, respectively.

Table II. Types of electives chosen by graduates of residency program

	On campus	*Off campus*	*Total*
Research	8	2	10
Oncology	4	6	10
Extra clinical	1	8	9
Surgical specialties	3	6	9
Maternal/fetal medicine, including genetics and ultrasound	5	3	8
Endocrinology	1	5	6
Pathology	5	1	6
Anesthesiology	1	4	5
Other	6	6	12
Total	34	41	75
Percent	45.3%	54.7%	

In general, we abided by the guideline that our residents would have 3 years of categorical rotations but not necessarily serve those rotations in any required identical order. This left 12 months for elective experiences. The elective experiences were expected to be worthy of a graduate study level, to be challenging, and also to be building blocks for the long-range growth of the individual.

In the preparation of our report on the residents' experiences, the resident graduates were surveyed. During the inclusive years 1970 to 1982, 53 residents completed our program. An additional one who finished a year later is included because he had been away for 2 years at the Centers for Disease Control and thus was a late finisher. The graduates were asked to react to their residency experiences in the light of what they have learned since they have left the residency. They were also asked to describe their current activities, their curricula vitae, and their future plans. Of the 54, 45 (83.3%) responded. The following report draws heavily on their replies and perceptions.

Stresses in a flexible system

Of the 54 graduates the great majority indicated their approval of the flexibility features.

However, a minority of graduates were critical of the elective system for various reasons. One said he had regrets at having failed to sign up for any electives. One expressed criticism of the program for having failed to apply pressure on him to seek elective experiences.* One superb and stalwart graduate said that he had no opportunity to sign up for electives because he was too busy carrying major patient care clinical loads, which

*My own recollection is that a large proportion of the residents were reluctant to sign up for any elective that they feared would dilute their categorical-type training experience!

Table III. Off-campus training sites for electives within the United States

Training site	*Area of study*	*No. of residents*
Atlanta—Cullen Richardson	Gynecologic surgery	2
Bowman Gray	Anesthesia	2
Case Western Reserve	Anesthesia	2
Columbia	Pathology	1
Duke	Endocrinology	2

University of California (Los Angeles)	Urology	1
Sloan-Kettering	Oncology	3
Centers for Disease Control		2
Total		20

indeed he was. Two believed the electives were not evenly distributed. Several found the frequent coming and going of residents and the variability of the size of the resident staff on duty at any one time to be unsettling.

One graduate provided the following insightful commentary on what a flexible program meant to him. "I believe UNC's graduates are able to consider alternatives to diagnosis and treatment because we had time and were encouraged to discuss problems rather than follow a 'cookbook'. . . . It remains imperative that UNC continue to choose residents that can handle this pressure of being more independent than residents of other programs . . . . The flexibility of our program is an excellent concept as long as residents or at least the majority of them are able to handle the stress and anxiety of accepting the responsibility that comes with flexibility."

Some positive feelings

Here are excerpts from other graduates' reports:

"The flexibility of the program at UNC allowed and encouraged me to function as an adult. My assessment is that many residency programs currently treat residents as children, rather than 26+-year-old individuals who have a good idea about what they need and want in order to grow personally and professionally. I would suspect that you will receive an argument against a flexible residency program—the statement that this sort of program would only work for a certain small segment and subset of the total group of GYN residents. While this may to some extent be true, I think the encouragement of self-motivation, assessment of character needs, and goals coupled with the guidance when needed from attendings within the basic structure of residency is the optimal situation."

". . . the program at UNC provided me with invaluable academic contacts and started academic habits . . ."

"The ease with which alternative educational activities blended with the program, the flexibility both with regard to internal and extramural scheduling, and the sincere (not just lip service) support and encouragement to broaden educational experience were unmatched by any program I interviewed at or have seen since. It still remains an ideal goal for programs I am involved with now."

"While I believe that the flexibility which you built into the program was exceedingly important, at least equally important in my mind was your strong support of the residents as they sought to take advantage of the opportunities you helped to create."

". . . the residency experience was more weighted to postgraduate education and less to technical training than other programs with which I am familiar. Nonetheless, I gained a good basic experience in clinical obstetrics and gynecology, such as surgical techniques and endocrinology, which has enabled me to continue my evolution as a specialist in infertility treatment, and which allows me to apply the skills in preventive medicine and epidemiology which I have also continued to pursue since the residency years."

"I am aware and will always be grateful that you squeezed me in after your five first-year slots were filled (to my chagrin!) . . .. The experience was freewheeling and intellectually exciting. You assembled a critical mass of superb people!"

Elective activities

Overall, the residents described 75 elective experiences that were meaningful to them. Thirty-four of these (45%) were electives undertaken on the campus of the University of North Carolina, and 41 (55%) were taken off campus (Table II).

A wide latitude was provided. Most commonly, the electives chosen tended to be grouped within a relatively few areas. Over half of the experiences described focused on five areas. Ten residents had one or more oncology electives. Ten had research electives, nine had surgical specialty electives, and nine had extra hands-on clinical electives. Eight chose electives relative to maternal and fetal medicine, including ultrasound, genetics, and neonatology. The remainder of the 75 electives varied widely in content and objective.

I will cite five unique electives: (1) A resident joined the Division of Medical Education for 3 months, as preparation for a career in academic medicine. (2) A resident established a university sex education course, which attracted wide interest and imitation. (3) Another resident established our departmental colposcopy clinic. (4) The same resident computerized our oncology records, a most demanding task but most produc-

tive in his future career. (5) Another resident undertook a heavy reading and study course during her 10-week maternity leave. This resulted in an article describing her own physical and emotional response to the pregnancy and delivery process. Publication of that article in turn led to multiple invitations for this graduate to participate extensively with women's education.

There were 20 elective experiences conducted at 12 off-campus sites in the United States (Table III). These included service at nine medical schools. Also included were three Galloway Oncology Fellowships at Sloan-Kettering, two 2-year stints away from the residency at the Centers for Disease Control, and two gynecologic surgical rotations in Atlanta.

Thirteen of our residents elected to do clerkships abroad (Table IV). Four of these were served at the University of West Indies in Kingston, Jamaica, as part of our Departmental participation in Project Hope. Three electives were served in London (one at University College Hospital and two at King's College Hospital), three at the Karolinska Institute in Stockholm, and one each in Vienna and Israel.

It appeared that prolonged furloughs or other absences from our campus did not deter the development of careers—in fact, it was quite the contrary with the Centers for Disease Control. Two of our residents had 2-year furloughs to work there, and a third joined our program at the completion of his 2-year appointment there. In each case the Centers for Disease Control proved to be an exceptionally stimulating and productive environmental influence. The resident who spent a year in Sweden learned research techniques that have helped his academic career.

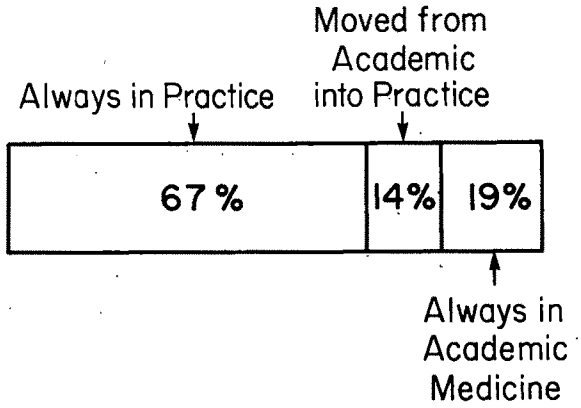

Fig. 2. Percentage of those graduates who went directly into practice, those who left academic departments to enter private practice, and those who have remained in full-time academic departments.

Outcomes of a flexible program

It is difficult to quantitate precisely the effect that flexibility and versatility in educational endeavor have on the final product, the graduate of such a residency program. As a general indication of overall results, I have elected to report on the following: membership and certification, a description of activities since leaving the residency and their relationships to medical school teaching programs, and evidence of scholarly activities as indicated by publications listed on curricula vitae.

Membership and certification. Of our 54 graduates, 51 are listed in the most recent directory of the American College of Obstetricians and Gynecologists. Fifty-one are Diplomates of The American Board of Obstetrics and Gynecology, with two more waiting to take Board examinations for the first time as soon as they are permitted to do so (Table V).

Four of our residents used elective opportunities in partial fulfillment of the Board requirements for specialties other than obstetrics and gynecology (Table VI). One resident had a 5-month elective in obstetric anesthesiology. At the completion of his formal residency, he achieved additional experience and ultimately became a Diplomate of The American Board of Anesthesiology. A second resident, having already served an internship in internal medicine, chose to use his 12

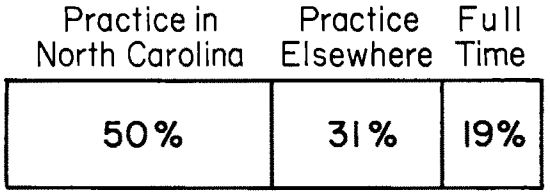

Fig. 3. Location of graduates in private practice or in full-time academic medicine. One-half of the graduates are now in practice in North Carolina.

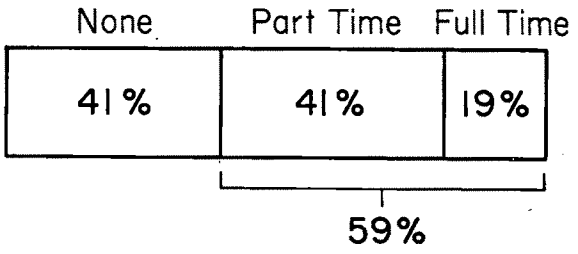

Fig. 4. Nearly three-fifths of the graduates now hold full-time or clinical teaching appointments.

months of electives entirely for internal medicine rotations, thus completing the formal training requirements that ultimately allowed him to become a Diplomate of The American Board of Internal Medicine. A third resident, having interned and then served a year of residency elsewhere that was followed by 2 years at the Centers for Disease Control, joined our program as a second-year resident for the final 3 years of his training experience. For his elective work he chose to obtain a Master of Public Health degree in our Public Health School, which ultimately helped him become a Diplomate of The American Board of Public Health and Preventive Medicine. A fourth resident also achieved a M.P.H. degree during his residency and was also able to become a Diplomate of the American Board of Public Health and Preventive Medicine.

Activities after leaving the residency. Of the 54 graduates, 36 (67%) went directly into private practice, while 18 (33%) went into full-time academic careers (Fig. 1). Of these, 16 were in medical school academic programs and two became permanent officers at the Centers for Disease Control, a career which, in my opinion, represents the equivalent of full-time academic activity.

With the passage of time, eight of those originally in full-time academic medicine moved from academic careers to full-time practice, leaving only 10 now in full-time academic careers (Fig. 2).

Where are they now? At present, 27 (50%) of the graduates of the program are in full-time private practice in North Carolina (Fig. 3). The primary mandate and mission of our training program was to produce well-trained specialists to serve the State, and it appears

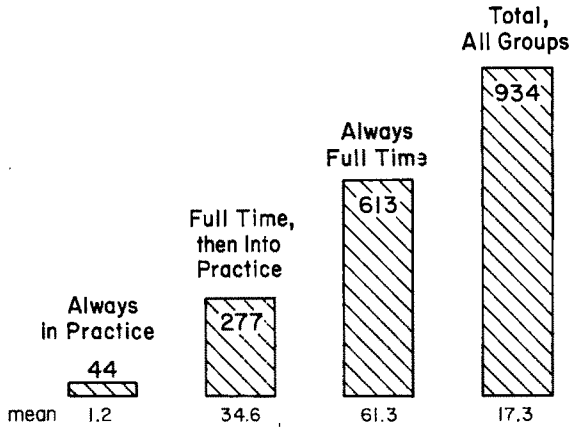

Fig. 5. Publications listed by graduates according to current professional activity. Of the 934 total listed publications, 613 appeared on the curricula vitae of the 10 full-time academicians.

Percent	7.4%

that this mandate has been well fulfilled. Seventeen (31%) are in private practice elsewhere, while 10 (19%) are still in full-time academic medicine

It is a matter of interest to note the current relationship between our 54 graduates and their teaching activities at various medical schools (Fig. 4). As mentioned, 10 are full-time staff members, but in addition to this, 22 (41%) hold part-time appointments for medical student and/or resident training in association with various medical schools across the country.* Thus 59% are currently performing teaching obligations in one of 12 medical schools. Four schools are in North Carolina: Bowman-Gray School of Medicine, Duke University, East Carolina University, and the University of North Carolina. The medical schools outside North Carolina are University of Arizona, Emory University, Hershey Medical Center, University of Mississippi, University of Nevada, Ohio State University, University of Oklahoma, and University of Oregon.

Publications. The publications to date as listed on

*The two Centers for Disease Control officers also have clinical appointments but are listed with the academic full-time quota and are not counted in the part-time teaching group.

the curriculum vitaes submitted by the various graduates are shown in Table VII. With very few exceptions, all items submitted are listed, including abstracts, papers in journals, chapters, books, and a scattering of articles appearing in non–peer reviewed publications. The 36 residents who have always been in private practice list a total of 44 publications or a mean of 1.2 publications per graduate. The individuals who started out in full-time academic careers but then went into full-time practice have published a total of 277 articles, a mean of 34.6 per graduate. The 10 individuals always in full-time academic medicine list a total of 613 publications, a mean of 61 per full-time graduate (Fig. 5).

In conclusion, it should be stated that a program as flexible as ours was during the decade of the 1970s would not be applicable to most other American training programs. There may be some features of our approach, however, that might find limited usefulness in the 1980s.

Response on the need for flexibility in academic obstetric-gynecologic residencies

James A. Merrill, M.D.
Seattle, Washington

It is appropriate that the American Gynecological and Obstetrical Society be concerned with resident education in our discipline and that emphasis be on the production of individuals who will further education and research. This is not the first time such an issue has been addressed here. In 1953 the American Gynecological Society appointed a committee to study the problem of recruitment of academic personnel for the specialty of obstetrics and gynecology. The work of that committee lead to the publication in 1961 of a report entitled "The Recruitment of Talent for a Medical Specialty." Many of the observations and recommendations in that report remain valid in 1985, 25 years later.

Although the recent American Gynecological and Obstetrical Society committees have addressed many of the same issues included in the earlier report, they have concentrated their interests on graduate medical education and preparation for academic careers. The American Gynecological and Obstetrical Society committee has stated ". . . If we are to develop different tracks for those preparing themselves for academic careers, the policies of The American Board of Obstetrics and Gynecology and the Residency Review Committee must be adjusted to accommodate them." This morning's symposium is a discussion of that opinion.

Many years ago the program director of a prestigious residency program proposed that graduates of his program should be certified by the Board without the necessity of examination. He reasoned that his program was at least 2 years longer than standard residency programs and that residents were selected because of their talent and interest in academic medicine. Unfortunately, that same year, graduates from that program failed the oral Board examination. Whatever its other policies, the Board has always maintained that individuals in academic positions should be at least as competent and preferably more competent than others and that their education should be at least as comprehensive and preferably more comprehensive than others. Certainly, there can be no quarrel with providing outstanding house officers with the opportunity to develop skills *beyond* those needed in practice, but there may be argument about developing other skills *instead* of those needed in practice.

Let us look at Board policy and see where it needs to be adjusted to accommodate academic programs. The second American Gynecological and Obstetrical Society committee has arbitrarily defined an academic program as one with the capability of preparing house officers to practice as specialist/consultant obstetrician/gynecologists. This essentially is what the Board seeks to evaluate in *every* candidate for certification. The

From The American Board of Obstetrics and Gynecology.

Board's definition of an obstetrician/gynecologist is "... individuals prepared to provide medical and surgical care for disorders that effect the reproductive system, the fetus or the newborn. These physicians have particular knowledge and skills which enable them to serve as consultants to physicians who practice in other areas of medicine." There may be a discrepancy between the ideal and the actual practice of obstetrics and gynecology. We must recognize the recurrent unanswered question of whether an obstetrician/gynecologist should be a specialist/consultant or a generalist with a "strong suit." The nature of the obstetrician/gynecologist has never been defined to everyone's satisfaction. For this reason, our approach to residency education is often schizophrenic—providing education neither for primary care providers nor for true consultants. However, the Board's definition seems to speak clearly to the question. To suggest different curricula or tracks for the basic preparation of academicians invites the development of different levels of certification.

The second American Gynecological and Obstetrical Society committee has identified five important factors that they believe prevent the development of high-quality residency programs and the recruiting and training of academic faculty. Of these, possibly three relate to the Board.

"1 . . . Academic programs have little opportunity to vary either the content or length of residencies to meet special or individual needs." Board policy prohibits neither. It does seem wise that modifications should be directed to expanding education, not contracting it, and that this should not be accomplished at the expense of uninvolved residents. Thus it may not be wise to mix curricula in the same program. The Board does have a policy regarding minimum duration of education but not maximum duration. Candidates must complete no less than 4 years, which must include at least 36 months' training in obstetrics and gynecology including a final year as Senior or Chief Resident. There is no prohibition against longer programs. Recently the Board has discussed lengthening the educational requirements. It has also discussed different levels of training and certification. There has not been great enthusiasm for either proposal but discussion continues.

"3 . . . There is no general agreement concerning the content of a program for developing specialist/consultant obstetrician/gynecologist and no specific requirements for graduation . . . " The Board is not directly involved in the content of residency programs, although it is indirectly involved in terms of the content of its examinations and the affidavit by which program directors attest to acquisition of certain knowledge and skills. The Board does agree that there is need to establish a defined base of knowledge and technical skills and is starting to address the issue of content. It is interested in finding out what currently exists in residency programs in terms of faculty, education, and training facilities. This information is not otherwise readily available. The Board is directly involved in both length and content of subspecialty fellowship programs which, of course, have as an important objective the preparation of academic faculty. The fact that the Board reviews and approves fellowships permits individualization and innovation more easily than can be accomplished in residency programs.

"4 . . . There is no effective method of evaluating the progress of house officers through such programs or of assuring the director that each has acquired the knowledge and developed the skills necessary to practice as a specialist." The Board recognizes this also as a problem for many programs. It is now in the process of developing a "pre-test" that will test for the basic information on which advanced knowledge and skills may be developed. This test may serve the purpose of providing program directors with helpful information necessary for the counseling, promotion, and graduation of residents.

Dr. Hendricks and Dr. Jaffe each have described an innovative approach to graduate medical education. Dr. Hendricks has described an individualized educational experience for residents, with an objective of serving as the basis for life-long growth of the individual, whatever his/her career. I do not see how this has been hampered by Board policy. His program has provided 12 months for electives. Within a 4-year program, as much as 1 year can consist of any sort of accredited education. He has used this opportunity to a maximum degree. His graduates have been eligible for Board examinations. Although there has been great "coming and going" of residents, the faculty at the University of North Carolina have managed to maintain an appropriate educational experience. The program has been successful, as have more rigid programs. This success is apparent, since essentially all graduates are Board certified, over half practice in North Carolina, a significant number hold full-time faculty positions, and the graduates have shown scholarly activity as measured by publications and medical school teaching assignments. Indeed, success may be greater than what Dr. Hendricks has reported, since it is difficult to measure all aspects of self-achievement. Thus this flexible program appears not to have been prevented by Board policy.

Dr. Jaffe proposes a modification of graduate medical education to encourage and improve research in this discipline. He considers this necessary because the academic area of obstetrics and gynecology is not realizing its potential. Approximately 3 years ago Dr. Jaffe made this proposal to the Board. After repeated

discussion, the outlined education was approved for one or two candidates. To the best of my knowledge the Board has not been notified that anyone has followed through with the approved curriculum. Dr. Jaffe is correct that the Board approved a program for individual circumstances and not categorically for the institution. The Board wished to observe the result of this experiment before authorizing it as a standard procedure.

The modifications in this proposal are quite different from those at North Carolina. This curriculum proposes to integrate residency and fellowship training and to do so by introducing some aspects of the fellowship training before completion of residency. Thus this proposal has its real impact on the policy governing fellowship rather than the residency. When this involves laboratory research, there is not likely to be a significant problem. However, when it involves clinical portions of the fellowship, there is reason for controversy. There has been a basic philosophy that subspecialization builds *on* basic knowledge and skills acquired during residency and not *instead* of them. Nonetheless, the Board has expressed a willingness to experiment with such a curriculum, recognizing that the research requirements of the three subspecialties are not similar. Indeed, the Board, in separate action, has accepted the proposal that extensive prior research experience may substitute in individual cases for 1 year of the required fellowship in reproductive endocrinology.

However, this sort of interdigitation between fellowship and residency, as well as any marked variation in resident rotation, raises the question of what should constitute the final or chief year of a residency program. Until recently, opinion has been that residency education should culminate in a time of independent decision-making and patient management and should be the final step in progressive acquisition of skills and knowledge. There may be reasons for change. The old pyramid system was dropped. If we are prepared to recognize a variation in the product of graduate medical education and in practice, then it might be appropriate to reconsider this system for some.

Although the Board may not subscribe readily to the concept of both academic and nonacademic programs, it is interested in any innovation that will improve the quality of education for obstetrician/gynecologists. Concern has been expressed that research in obstetrics and gynecology may have been diminished by the substitution of clinically oriented subspecialty training programs for the laboratory training that otherwise might have been pursued by those entering academic careers. Therefore, three studies were conducted by the Board, addressing research in obstetrics and gynecology. One was a study of scholastic ability of residents, another was the analysis of a questionnaire sent to everyone who had been in a subspecialty fellowship, and the third was an analysis of a questionnaire sent to all chairmen of medical school departments of obstetrics and gynecology. The response to the questionnaires was 71% and 81%, respectively.

The scholastic ability of those who finished obstetrics and gynecology residencies in 1983 and 1984 was studied. To the extent that scholastic ability is measured by performance on National Board of Medical Examiners Part I and Part II examinations, residents in obstetrics and gynecology, on the average, had slightly less of that ability than national norm groups who took the same examinations, a finding remarkably similar to the American Gynecological Society study reported in 1961.

Between 1974 and 1984 the mean number of full-time faculty members in departments of obstetrics and gynecology doubled. Ninety-three percent of medical school chairmen report trained subspecialists in one or more subspecialties, and 60% of them report trained subspecialists in all three areas. However, approximately one fourth of the departments indicate no research funding from the federal government, and one fourth of the schools report no research funding from foundations. Over one half of the responding department chairmen do not plan to recruit a candidate with an M.D. degree to spend 50% of his time in laboratory research during the next 5 years.

Sixty percent of prior fellow respondents have full-time faculty appointments, and 16% are in private practice. Approximately 50% of their professional time is devoted to the subspecialty. The mode and median time devoted to research is 10%. Most research is clinical research, and 57% of respondents do no laboratory research. Two thirds of the subspecialist respondents have never filed research grants with the federal government. However, of those who have submitted grants, 64% of the grants were approved and 34% of the grants were funded. One fourth have published no papers since completing fellowships.

I agree with Dr. Jaffe that academic obstetrics and gynecology is not realizing its potential. There are many factors impacting on this, not the least of which are financial. Many of the problems identified by Howard Taylor's American Gynecological Society Committee, 25 years ago, are still with us. Although I consider the attitude and priorities of department leadership the most important, innovation and flexibility in graduate medical education certainly are important. However, I do not believe that either is prevented or inhibited by Board policy. The Board may be somewhat rigid but not ossified! Tracks for academicians can be worked out, but they must not hamper other residents. Both Dr. Jaffee and Dr. Hendricks identified this as a potential disadvantage. There can be more than one kind

of residency training program so long as each is a good one. Rather, I think the limitation to innovation and flexibility in graduate medical education is in the imagination of our leaders and in the lack of a clear definition of the specialty. Exciting and imaginative training programs are difficult to conceive and difficult to administer. In 1955 the American Gynecological Society Research Subcommittee stated ". . . The nature of this specialty makes it well nigh impossible for the practitioner to have much consecutive time for reflection, reading or investigation and it is the genuine impression of this committee that our field has not in the past 25 years attracted its share of the scholars. It is entirely possible that the research status of our residents simply reflects the research activity of their leaders." The success of the residency programs at Chapel Hill and San Francisco and of many other fine programs may reflect not so much the flexibility and individualization of the curriculum, as it does the imagination and enthusiasm of the faculty.

Response on the need for flexibility in academic obstetric-gynecologic residencies

Roy M. Pitkin, M.D.
Iowa City, Iowa

Contained in the invitation to participate, on behalf of the Residency Review Committee, in this program on flexibility in academic residencies was the suggestion that my discussion include the "reasons for the presumed rigidity of the two accrediting bodies in considering requests for deviations from the basic requirements." I am not certain precisely what this means, but I assume no one would seriously suggest that there ought to be two sets of standards, one for residencies designated by some means as "academic" and the other for the rest, for such would clearly be in conflict with all traditions of fairness as well as with the constitutional provisions for equal protection and due process.

If, as seems more likely, the type of flexibility desired is that described by Drs. Jaffe and Hendricks, I wonder if the problem may not be more imaginary than real. In comparing each of these programs, one operative for the period 1968 to 1980 at the University of North Carolina and the other proposed for the University of California (San Francisco), with the current Special Requirements, I can find little if any intrinsic conflict. Let me cite a few examples.

Perhaps the most specific (and therefore the least flexible) of the Special Requirements is that relating to length of graduate medical education in this discipline: "A resident must have a minimum of 4 years of approved clinically oriented graduate medical education, of which at least 3 years must be entirely in the specialty of obstetrics-gynecology." Dr. Hendricks indicates that the general guideline at the University of North Carolina was for 3 years of "categorical rotations," leaving a year for electives; parenthetically, one wonders how often residents spent as much as a year on electives. Dr. Jaffe's proposal is not quite as specific, but I do not believe it is inconsistent with this requirement.

The Special Requirements are also quite specific about the senior or chief residency year, reflecting the Residency Review Committee's belief that this period represents the most important segment of the residency. It must consist of 12 months of clinical experience, and electives or extramural rotations are not permitted without prior Residency Review Committee approval. Neither Dr. Jaffe nor Dr. Hendricks addressed the senior resident year specifically and I wonder how their proposal would square with the present stipulations.

If clinical training is interrupted to send residents off for research or other elective experience whence they later return to reenter the clinical cycle, the program might find itself at times over its approved complement. But this risk also may be more theoretical than real, for Dr. Hendricks has shown that in only 1 year of 13 did the University of North Carolina program exceed its approved number of graduates and that year was flanked on either side by under-quota years.

The Residency Review Committee has in my judgment acted quite flexibly with respect to requests for a temporary increase of one in total resident complement. Such requests are considered by the Secretary and Chairman and are approved expeditiously as long as the program is not on probation, the clinical volume adequate to accommodate another resident, and the basis of the request reasonable. With respect to the last, an effort to facilitate a resident's desire for prolonged research experience would surely be regarded as reasonable.

In Dr. Jaffe's proposal, some trainees may interrupt clinical training for prolonged periods (for example, a year or longer) and then reenter, raising the potential for conflict with the Special Requirement that "programs of different lengths or quality in the same institution will not be approved." However, any problem can be circumvented easily if the individual during this

From the Residency Review Committee.

Other Board/graduate degree (n)	4	5

time is not designated as a resident. Indeed, this seems to have been the practice at the University of North Carolina, for Dr. Hendricks speaks of residents being "furloughed" to the Centers for Disease Control.

Terms like "flexibility" and "rigidity" are, like beauty, actually in the eye of the beholder. Whereas the Residency Review Committee may be viewed by many as inflexible, I am unable to find any intrinsic conflict between the Committee's published standards and the concepts of flexibility put forth in these essays. I would expect that all could find agreement with the peroration of the Special Requirements: "It is not essential or desirable that all training programs be identical in structure or function. It is, however, mandatory that each residency program provide quality education and experience for each of the residents completing the program."

This concludes my response on behalf of the Residency Review Committee. I would like, however, to continue the discussion as an individual program director. Dr. Hendricks' description of the program he developed at the University of North Carolina spurred my interest in compiling similar data from graduates of the University of Iowa program during the same time (1970 to 1982). The two institutions are similar in many ways (state university, full-time faculty, university hospital base, small town, etc.). Moreover, I believe the Iowa faculty, led for the first half of that period by Dr. William C. Keettel, would endorse wholeheartedly at least six of the seven principles Dr. Hendricks enunciated in his preamble. There might have been some difficulty embracing the second principle, which concerns rearranging time and geography to help a single resident's career, for the Iowa curriculum during the period in question was an utterly rigid, lock-step arrangement by which all residents followed precisely the same assignment schedule. Thus it was rigid where the University of North Carolina program was flexible, and I thought the comparison might prove interesting.

My data are based on the 66 graduates of the University of Iowa residency program during the years 1970 to 1982. The vast majority (78%) of those responding to the questionnaire indicated that the lack of flexibility in the Iowa residency was a good idea, and most of the rest (16%) thought it made no difference; only 6% saw it as any disadvantage. Several commented to this point and one, a successful departmental chairman, stated "In my experience, students and residents tend to choose pleasant, nonstressful electives. A good example is the waste of time of some of the overspecialized electives for senior medical students."

Table II. Current status of 1970 to 1982 graduates

	University of North Carolina	*University of Iowa*
Full-time academic career	19	21
Private practice in state	50	38
Private practice elsewhere	31	41

Table III. Publications by 1970 to 1982 graduates

No. of publications	*University of North Carolina*	*University of Iowa*
>100	2	2
51-100	7	2
26-50	3	2
6-25	6	16
1-5	10	22
0	26	14

Table I compares certain aspects of the two programs. The only very striking difference is in attrition. Dr. Hendricks has indicated that the 54 University of North Carolina graduates of that period reflected 83% of those who started training whereas only 3% of the number who began the Iowa program failed to finish. All but two of the Iowa graduates are certified by the American Board of Obstetrics and Gynecology, and those two are 1982 graduates who recently completed 3-year subspecialty fellowships. Four University of North Carolina residents used their elective time to fulfill, partially or completely, requirements for other board certification and/or graduate degrees. Without any such option during residency, five Iowa graduates registered similar accomplishments following residency (certification in pathology and anesthesiology, graduate degrees in microbiology, education, and preventive medicine).

Table II summarizes the current status of graduates of the two programs. The proportions in full-time academic medicine and private practice, both inside and outside the respective states, are similar. Of private practitioners, 39% of University of North Carolina graduates and 38% of Iowa alumni hold clinical teaching appointments in medical schools.

The number of publications by graduates is summarized in Table III. University of North Carolina

graduates have been somewhat more productive than have Iowa alumni, at least as reflected in the number of highly productive individuals. As a result, the mean number of publications per graduate was 17 for North Carolina and 12 for Iowa. On the other hand, more Iowa graduates have published at least one paper. At Iowa, as at the University of North Carolina during this period, there was no requirement regarding research or publication.

This comparison of two residency programs with somewhat different philosophies regarding flexibility/rigidity of curriculum indicates no substantial differences in the outcomes measured. Perhaps what is at issue here is flexibility of *thought* rather than of *curriculum*. I agree wholeheartedly with Dr. Hendricks' educational imperative that "the basis for patient management should start with an analytic approach rather than simply a dogmatic one."

We have all heard the old axiom about many ways of skinning a cat. If one starts with an intact cat and uses any of several appropriate means of cat-skinning, then one will likely end with a skinned cat.

Discussion

DR. ROBERT B. JAFFE, San Francisco, California. Drs. Merrill and Pitkin are extraordinarily articulate and persuasive. Let me just ask them a specific question. If either of the two individuals whose curricula vitae and bibliographies I showed to you were to apply to my program next year, may I commit to them in advance the type of flexible program integrating clinical training and research which I have suggested?

DR. JAMES A. MERRILL. Yes.

DR. ROY M. PITKIN, Iowa City, Iowa. The Residency Review Committee does not review and approve individuals. It accredits programs. If your program is accredited, you can make an agreement with an applicant that he complete that program.

When the program comes up for review, it will be evaluated as a program but not as it might affect individuals.

DR. MORTIMER G. ROSEN, New York, New York. I listened to this program with a great deal of interest and enjoyment, since one of the reasons I went into this specialty was not to be a researcher but to be an educator, and I have since changed and have even become a little more flexible.

I think there was an emphasis on the words "flexibility" and "rigidity," and I believe that is misplaced activity. As I heard the discussions, what I was impressed with was the originality of the program directors and the interest of the discussants, all of whom had been residency program directors with different plans producing different programs.

Then I thought that today most programs are just struggling to survive, and indeed, residency programs are under a tremendous amount of pressure today to deliver patient care, to produce educators, and to produce future scientists. Part of my comments will reflect this more broad charge, because I am going to muddy the waters of this discussion.

As I have just been at Columbia for 8 weeks, I will point out to you that in that system, the residency program is in the hands of a junior individual who just completed a training program in July. The only person who is as junior in our educational program is the Director of the Medical Students Educational Program. Both are well motivated, but quite junior. This may reflect the interest of our system in education. However, if we want educational and training programs to be a bit more superior, then we will have to recognize their leaders and their commitments—or indeed the program directors will not remain in that academic pathway very long.

Dr. Merrill made a comment that I think we should make note of. It would appear that the quality of performance of the individuals whom we have trained over the last 20-some years has really not changed. Although we would like to see the quality of the trainees improve, these numbers which Dr. Merrill has quoted really do not reflect a trend. The data lead me to the next statement. While this is an educational discussion, I would hope that you will permit me this statement made as an individual who has had continuing National Institutes of Health grant support for many years. In my travels to various hospitals in the United States I have often been asked to look at their problems in obstetrics. Inevitably when I look at the problems in obstetrics, I open the surgical book and also look at the problems in gynecology. I learned after a while that it was not surprising to find that clinical patient care "problems" were endemic within obstetrics, also were present in gynecology, but indeed, not as easily recognized as noting a cesarean birth rate.

Thus to muddy the waters here, what I would point out is that while there is a problem in improving the quality and the number of people going into the academic system and into the research pathway, which I am quite dedicated to improving and increasing, I would also point out to you that the clinical practice of obstetrics and gynecology is having just as much difficulty, and that problem is also important. Rather than to provoke individuals to respond in individual ways, do not focus alone on one part of our system, because very frankly I think we are just as much in need of improving clinical patient care as we are of attracting investigators into the research field. That too needs some rethinking.

DR. DENIS CAVANAGH, Tampa, Florida. I am sure, although we have some different interests, we all have a common goal, and the common goal is to improve the discipline of obstetrics and gynecology.

The first point is to have solid clinical residency programs. The American Board of Surgery has now decided that one has to have hysterectomies as part of the training before one can be certified in general surgery. This means that our residents are going to have to be

better in the operating room than they have been in the past. For this reason I agree with Dr. Merrill. We really have to have a solid core of residency training, on which to build the rest of our postgraduate education.

I think that the 3-year fellowships with a year in the laboratory is a very good plan, it being very important to orient the subspecialist as to the importance of scientific basis, whatever his/her career choice.

Third, I think that the Kennedy Foundation Fellowships really should be career awards. These career awards to truly distinguished and promising young people should provide sufficient financial inducement to keep them in academic medicine.

And fourth, we have to get busy and gain more influence nationally. The National Institute of Child Health and Human Development has just appointed a pediatrician again as the director, and we just heard that only 5% of the Institute's grants are going to obstetricians and gynecologists at this time. Is this going to get even worse?

The American Gynecological and Obstetrical Society and the American College of Obstetricians and Gynecologists (which has largely become just another union) really have to get into the act, and we have to get more influence at the National Institute of Child Health and Development and the other funding agencies in Washington, D.C. Without adequate funding for their research our young career scientists will become discouraged, and all our efforts to improve recruitment to academic obstetrics and gynecology will be doomed to failure.

The relation of angiotensin-converting enzyme to the pregnancy-induced hypertension–preeclampsia syndrome

John W. Goldkrand, M.D., and Armando M. Fuentes, M.D.
Albany, New York

Angiotensin-converting enzyme, the polypeptide that converts angiotensin I to angiotensin II, was measured in the serum of 114 pregnant women who had normal blood pressure, pregnancy-induced hypertension–preeclampsia, and chronic hypertension with or without pregnancy-induced hypertension. Angiotensin-converting enzyme levels were unrelated to weeks of gestation. The angiotensin-converting enzyme levels were similar in normotensive women (21.1 ± 6.9 units/ml), women with chronic hypertension without pregnancy-induced hypertension (23.1 ± 2.7 units/ml), and patients with pregnancy-induced hypertension where magnesium sulfate (22.6 ± 8.7 units/ml) had been administered prior to angiotensin-converting enzyme assay, but these values were significantly less than those in patients with pregnancy-induced hypertension with no magnesium sulfate (29.1 ± 6.5 units/ml) therapy and in women with chronic hypertension with superimposed pregnancy-induced hypertension (30.7 ± 4.4 units/ml) ($p < 0.005$). Maternal venous and umbilical venous and arterial angiotensin-converting enzyme levels were as follows: The maternal venous level was less than the cord venous level and greater than the cord arterial value. Neither neonatal size nor twin gestation influenced the angiotensin-converting enzyme levels. Patients with diabetes mellitus had variable angiotensin-converting enzyme values regardless of the status of the blood pressure. The physiologic theories of blood pressure control in pregnant women are discussed in relation to the renin-angiotensin, bradykinin, and prostaglandin systems. (Am J Obstet Gynecol 1986;154:792-800.)

Key words: Angiotensin-converting enzyme, pregnancy-induced hypertension–preeclampsia, chronic hypertension with or without superimposed pregnancy-induced hypertension, vascular responsiveness to pressor substances

". . . It is the increased responsiveness of the arterial system to pressor substances which probably causes the generalized vasoconstriction and hypertension of preeclampsia."[1]

Hypertensive disease of pregnancy complicates approximately 6% to 10% of all pregnancies and is responsible for increased maternal and perinatal mortality and morbidity. Investigations to define the pathophysiology of the pregnancy-induced hypertension–preeclampsia syndrome have as common factors the renin-angiotensin system and the vascular responsiveness to pressor substances. Angiotensin-converting enzyme is a polypeptide with a molecular weight of 140,000 daltons, which is secreted by the vascular endothelium and converts the decapeptide angiotension I to the octapeptide angiotensin II, one of the most potent vasoconstrictors.[2, 3] Abdul-Karim and Assali[4] demonstrated that normal pregnant women develop a refractoriness to the pressor effects of infused angiotensin II.[5] Angiotensinase, which inactivates angiotensin II, has been found to increase throughout the course of pregnancy[4] and may contribute to this refractoriness. Gant et al.,[3] Talledo et al.,[6] and Chinn and Dusterdieck[7] confirmed the increased sensitivity to infused angiotensin II in patients with or destined to develop the pregnancy-induced hypertension–preeclampsia syndrome. In normal pregnancy, no increased angiotensin-converting enzyme levels were noted by Parente et al.,[5] while Oats et al.[2] showed a steady increase in the angiotensin-converting enzyme level from 30 weeks' gestation until term. In a preliminary study, we demonstrated significantly increased angiotensin-converting enzyme levels in patients with pregnancy-induced hypertension when compared with those in normal pregnant women.

Since angiotensin-converting enzyme appears to have a pivotal role in the renin-angiotensin system by converting angiotensin I to angiotensin II, it seemed appropriate to undertake the present investigation—to study clinically the relationships of angiotensin-converting enzyme concentrations in pregnant patients who are normotensive and those with the pregnancy-induced hypertension–preeclampsia syndrome and patients with chronic hypertension with or without superimposed pregnancy-induced hypertension.

Material and methods

Definitions

Pregnancy-induced hypertension. Pregnancy-induced hypertension was defined as an absolute blood pressure of 140/90 mm Hg or an increase in systolic blood pressure of 30 mm Hg and/or an increase in diastolic blood pressure of 15 mm Hg on two occasions, 6 hours apart, after 24 weeks' gestation.

Preeclampsia. Preeclampsia was defined as a triad of (1) the blood pressure changes noted in pregnancy-induced hypertension, (2) 24-hour urinary protein levels of ≥300 mg, and (3) generalized edema. For the purposes of this study, pregnancy-induced hypertension and preeclampsia were combined as components of a single abnormal physiologic and clinical syndrome.

Chronic hypertension. Chronic hypertension included the elevation in blood pressure noted for pregnancy-induced hypertension occurring either before pregnancy or before the twentieth week of gestation.

Superimposed pregnancy-induced hypertension. Superimposed pregnancy-induced hypertension was defined as clinical findings of pregnancy-induced hypertension in patients previously diagnosed as having chronic hypertension.

Magnesium sulfate. Magnesium sulfate was administered by the intravenous route with an initial bolus of 2 to 4 gm, followed by 2 gm/hr to maintain a serum magnesium level of 4.5 to 6.5 mg/dl. Patients were treated at the physician's desire in mild pregnancy-induced hypertension but routinely with severe pregnancy-induced hypertension–preeclampsia (blood pressure > 160/100 to 110 mm Hg). Notation was made of all patients receiving magnesium sulfate before angiotensin-converting enzyme levels were determined, and these were analyzed separately.

Mean arterial blood pressure. Mean arterial blood pressure was measured as:

$$\text{Diastolic blood pressure} + \frac{(\text{systolic blood pressure} - \text{diastolic blood pressure})}{2}$$

This was measured before 20 weeks' and after 24 weeks' gestation in patients with normal blood pressure, pregnancy-induced hypertension–preeclampsia, and chronic hypertension.

Patients. Pregnant women were selected at random from the obstetric population delivered of their infants at the Albany Medical Center Hospital from January 1, 1984, through July 1, 1985. The patients were studied in the third trimester of pregnancy on the basis of a clinical diagnosis of normal blood pressure, pregnancy-induced hypertension–preeclampsia, and chronic hypertension with or without pregnancy-induced hypertension (Table I). Samples of blood for measurement of serum angiotensin-converting enzyme levels were drawn either singly, about the time of delivery, or during antepartum evaluation. In addition, serum uric acid and blood urea nitrogen were determined. In 12 cases, nearly simultaneous samples for maternal venous and umbilical venous and arterial angiotensin-converting enzyme levels were obtained. Normotensive control patients were chosen at random either at the time of labor and delivery or elective cesarean section or antepartum in the third trimester of pregnancy. The 114 patients were drawn from a population of about 3325 women delivered of their infants during the study interval. The mean maternal ages were 25 ± 7 years in the normal population and 26 ± 7 years in the hypertensive population (p = NS). Racially, the groups were the same with 81% Caucasian, 16% black, and 3% Indian or Oriental. At the Albany Medical Center, approximately 15% of the deliveries are in patients who are transported in from a 17-county regional perinatal network. In the study, 30% of the patients represented maternal transports, since hypertensive disease is a major indication for transport. Both the normal and hypertensive patients had a mean gravidity of 2, and 48% were primigravid. Twenty-four percent of the patients smoked at least one half a pack of cigarettes a day—29% hypertensive women and 71% normal women. The mean weight gain in pregnancy was 33 pounds for both groups. The normotensive patients were delivered at a mean of 38 weeks' gestation, and the hypertensive patients at a mean of 36 weeks' gestation ($p < 0.025$). The babies delivered of normotensive women were heavier (mean 3015 gm) than those of hypertensive women (2570 gm) ($p < 0.02$), while the placental weights were not significantly different. There was no difference in the distribution of the sexes of the neonates. The hypertensive group tended to have a higher rate of cesarean delivery (55%) than the normotensive women (37%), but this was not statistically significant. Baseline control values of serum angiotensin-converting enzyme and uric acid were

Table I. Patient population: Distribution by diagnosis

Diagnosis		*n*
Normotensive		49
Pregnancy-induced hypertension–preeclampsia		57
No magnesium sulfate	36	
With magnesium sulfate	21	
Chronic hypertension		8
No pregnancy-induced hypertension–preeclampsia	5	
Superimposed pregnancy-induced hypertension–preeclampsia	3	
Total		114
Nonpregnant		9

There were five sets of twins in pregnancies with pregnancy-induced hypertension–preeclampsia and two in pregnancies without pregnancy-induced hypertension–preeclampsia.

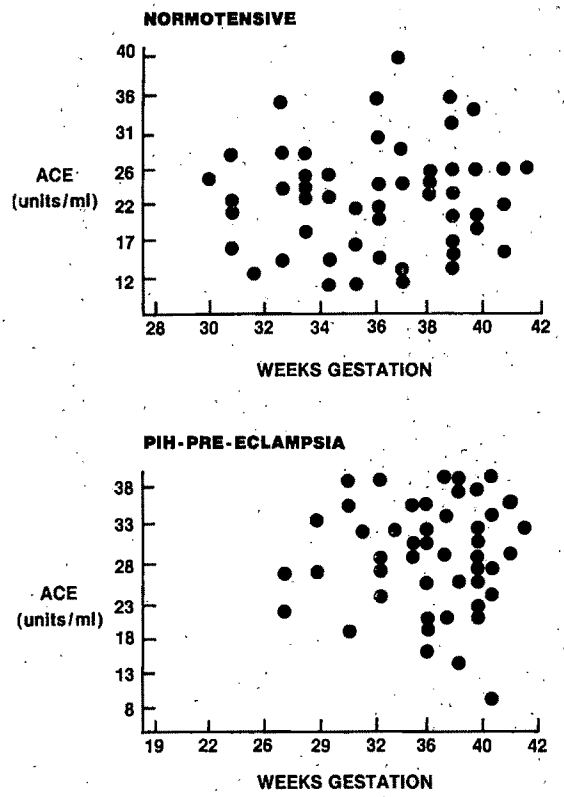

Fig. 1. Angiotensin-converting enzyme *(ACE)* levels in the normotensive and pregnancy-induced hypertension–preeclampsia populations compared by the week of gestation when samples were drawn [normal: $r^2 = 0.003$, $y = 25.5 + (-0.106x)$; pregnancy-induced hypertension: $r^2 = 0.027$, $y = 17.7 + 0.27x$].

measured in nine normotensive, nonpregnant, non–hormone-using women, aged 24 to 34.

Neonates. All babies were evaluated by the Neonatology Staff irrespective of the study. The neonatal complications were sepsis (two in normotensive mothers and two in hypertensive mothers) and respiratory distress syndrome (one in the normotensive group and nine in hypertensive women). One infant of a mother with pregnancy-induced hypertension died of congenital heart disease. The overall perinatal mortality was 8.7 per 1000 live births.

To correct for possible birth weight differences among babies born at differing gestational ages, all babies were classified as appropriate for gestational age, small for gestational age, and large for gestational age according to the University of Colorado data, which were used by the Albany Medical Center Neonatology Group. Mothers with pregnancy-induced hypertension were delivered of more small for gestational age babies than were those who were normotensive ($p < 0.025$) (normotensive: appropriate for gestational age, 44; small for gestational age, three; large for gestational age, four; hypertensive–pregnancy-induced hypertension: appropriate for gestational age, 35; small for gestational age, 14; large for gestational age, seven).

Laboratory. The angiotensin-converting enzyme levels were measured according to the method of Lieberman[8] in the Chemistry Laboratory of the Albany Medical Center Hospital. This method utilizes a spectrophotometric analysis of the free hippuric acid cleaved from hippuryl-L-histidyl-L-leucine by angiotensin-converting enzyme. The blood was drawn in a 10 ml clot tube, spun, and then kept either refrigerated or frozen at −4° C before analysis. The interassay variability is ±5 units/ml. The blood urea nitrogen and uric acid determinations were performed in the same laboratory.

Statistics. Data were analyzed by standard statistical procedures on the VAX computer with the use of mean, standard deviations, χ^2, and Student's t test.

Results

Angiotensin-converting enzyme levels (Figs. 1 and 2). The determinations of serum angiotensin-converting enzyme levels obtained from the twenty-fifth to the forty-third week of gestation from all patients with normal blood pressure and those with the pregnancy-induced hypertension–preeclampsia syndrome were examined graphically (Fig. 1) against the week of gestation during which the samples were obtained. The angiotensin-converting enzyme levels appeared to be independent of gestational age. Nonpregnant women had an angiotensin-converting enzyme level of 29.3 ± 6.4 units/ml, which was significantly greater than that of pregnant women with normal blood pressure (21.1 ± 6.9 units/ml, $p < 0.005$) (Fig. 2.). Among those women with the pregnancy-induced hypertension–preeclampsia syndrome, those receiving magnesium sulfate before the measurement of angiotensin-converting enzyme had levels of 22.6 ± 8.7 units/ml, which was lower than that of those with no magnesium sulfate therapy (29.1 ± 6.5 units/ml, $p < 0.005$). The angiotensin-converting enzyme level in women with chronic hypertension without pregnancy-induced hypertension (23.1 ± 2.7 units/ml) was less than that of those with superimposed pregnancy-induced hypertension (30.7 ± 4.4 units/ml, $p < 0.005$) and bore the same relationship as the patient with pregnancy-induced hypertension with or without magnesium sulfate therapy. Normotensive women had angiotensin-converting enzyme levels similar to those of patients with chronic hypertension and no pregnancy-induced hypertension and those with pregnancy-induced hypertension and magnesium sulfate therapy.

There were seven sets of twins; five had mothers with pregnancy-induced hypertension and two mothers were normotensive. When the angiotensin-converting enzyme levels were compared to those of the women

Table II. Paired samples of maternal and cord blood angiotensin-converting enzyme levels, with samples obtained nearly simultaneously from each compartment

	Angiotensin-converting enzyme		
Diagnosis	*Maternal venous (units/ml)*	*Umbilical cord venous (units/ml)*	*Umbilical cord arterial (units/ml)*
Pregnancy-induced hypertension–preeclampsia, no magnesium sulfate	37.8	37.4	34.5
	34.0	27.2	
	37.8	37.8	
	37.8	47.7	
Normotensive	23.7	21.0	13.7
	22.0	37.0	22.0
	11.6	23.0	24.4
	21.0	10.2	
	19.0	22.2	18.8
	18.6	20.4	
Pregnancy-induced hypertension–preeclampsia with magnesium sulfate	19.7	21.7	15.7
Diabetes (Classes D to R), pregnancy-induced hypertension–preeclampsia	35.7	43.7	

With magnesium sulfate = Treated with magnesium sulfate before angiotensin-converting enzyme determination; no magnesium sulfate = no magnesium sulfate given before angiotensin-converting enzyme determinations. Results show: Maternal venous value was less than the cord venous value and greater than the cord arterial value.

with singleton pregnancies with or without pregnancy-induced hypertension, there were no differences.

The mothers whose babies were classified as small for gestational age (n = 17) had angiotensin-converting enzyme levels that were comparable to those of mothers of normal-weight babies from both the normotensive and hypertensive groups.

The study population had 10 patients with diabetes mellitus complicating pregnancy: (1) normotensive, Class A (n = 4) and Class D (n = 1); (2) pregnancy-induced hypertension, Class B (n = 2), Class C (n = 1), and Classes D to R (n = 1); (3) chronic hypertension, Class R (n = 1). There was a wide range of angiotensin-converting enzyme values in those patients, from 14.6 to 45.3 units/ml, which did not appear to correlate with either the diabetic classification or the normotensive-hypertensive category.

Paired samples, obtained nearly simultaneously, were drawn from the maternal venous and umbilical venous blood of 12 patients and umbilical arterial blood in six maternal/neonatal sets (Table II). The values, regardless of the status of blood pressure, showed a rather uniform relationship: The maternal venous value was less than the cord venous value and greater than the

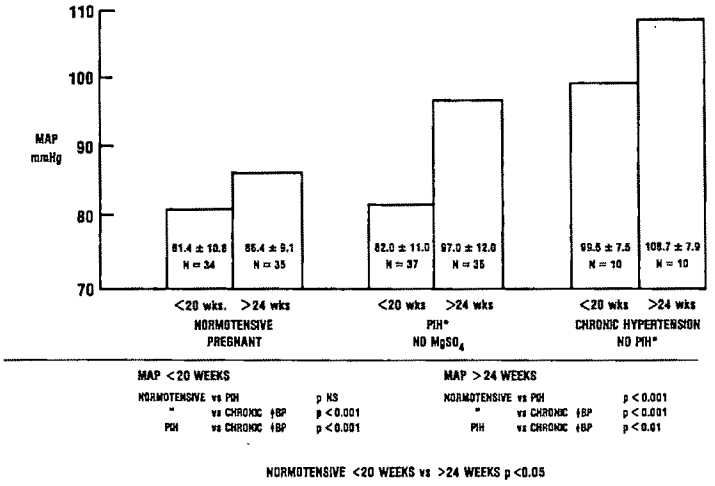

Fig. 3. Mean arterial blood pressure *(MAP)* in normotensive women, women with pregnancy-induced hypertension *(PIH)* in whom magnesium sulfate was not given, and patients with chronic hypertension before 20 weeks and after 24 weeks of gestation.

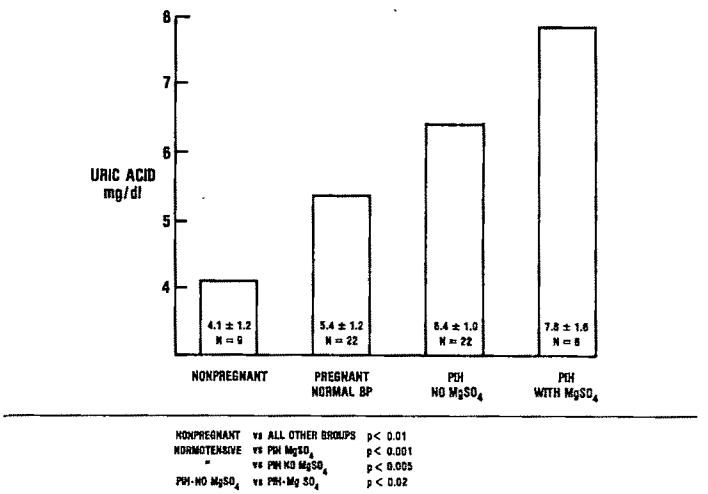

Fig. 4. Uric acid levels in patients according to the status of the blood pressure. $MgSO_4$ = Treated with magnesium sulfate before angiotensin-converting enzyme determination. *No* $MgSO_4$ = No magnesium sulfate given before angiotensin-converting enzyme determination.

cord arterial value. In four pregnancies, amniotic fluid was obtained for angiotensin-converting enzyme determination and was consistently <5 units/ml.

Mean arterial blood pressure (Fig. 3). The mean arterial blood pressure was calculated in normotensive women, women with pregnancy-induced hypertension–preeclampsia, and women with chronic hypertension before the twentieth week and after the twenty-fourth week of gestation. In each group, the mean arterial blood pressure at >24 weeks was significantly higher than that at <20 weeks (normal blood pressure, $p < 0.05$; pregnancy-induced hypertension, $p < 0.001$; chronic hypertension, $p < 0.001$). The mean arterial blood pressure at <20 weeks was the same in the normotensive group and the group with pregnancy-induced hypertension, and both were less than that from patients with chronic hypertension ($p < 0.01$).

Uric acid and blood urea nitrogen. The uric acid level (Fig. 4) in nonpregnant women (4.1 ± 1.2 mg/dl) was less than the third-trimester level in normotensive women (5.4 ± 1.2 mg/dl, $p < 0.01$). Patients with pregnancy-induced hypertension and not receiving magnesium sulfate had higher levels of uric acid (6.4 ± 1.0 mg/dl) than the normotensive women ($p < 0.005$), while those with pregnancy-induced hypertension and receiving magnesium sulfate had the highest values (7.8 ± 1.6 mg/dl, $p < 0.001$).

The blood urea nitrogen of normotensive women (9.2 ± 2.4 mg/dl) was less than that of patients with pregnancy-induced hypertension without (12.2 ± 3.9 mg/dl) or with (14.7 ± 6.8 mg/dl) magnesium sulfate

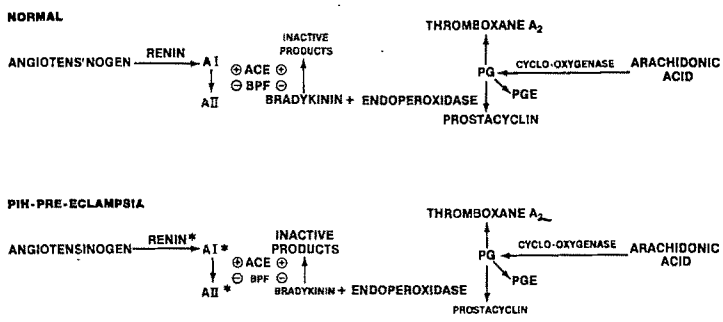

Fig. 5. Theoretical interrelationship of the renin-angiotensin system, bradykinin, and the prostaglandins in pregnant patients with normal blood pressure and those with the pregnancy-induced hypertension *(PIH)*–preeclampsia syndrome. * = Increased (?). *ACE* = Angiotensin-converting enzyme. *BPF* = Bradykinin-potentiating factor. + = Stimulates reaction. − = Slows or blocks reaction.

($p < 0.001$). However, in the two groups of patients with pregnancy-induced hypertension, there were no differences.

Comment

This study demonstrates that serum angiotensin-converting enzyme levels show significant changes in pregnancies that are complicated by hypertensive diseases when compared with pregnancies in normotensive women. We have shown that there is no correlation ($r = 0.05$) when the angiotensin-converting enzyme levels are compared to week of gestation (Fig. 1). This agrees with Parente et al.,[5] but other authors[2, 9] have described a steady increase in angiotensin-converting enzyme after 30 weeks of gestation. That our nonpregnant angiotensin-converting enzyme levels are considerably higher than those from normal pregnancy confirms the literature[2, 9]; these levels are comparable to those in patients with pregnancy-induced hypertension not requiring magnesium sulfate and those with chronic hypertension and with superimposed pregnancy-induced hypertension (Fig. 2). Abdul-Karim and Assali[4] found that the nonpregnant woman was more responsive than the normotensive pregnant woman to an infusion of angiotensin II. They stated that the beneficial effect of pregnancy on hypertension was related to elevated angiotensinase activity and an increased destruction of angiotensin II. The literature seems to favor decreased angiotensin II levels in patients with pregnancy-induced hypertension,[7] but Symonds et al.[10] reported increased angiotensin II levels in preeclampsia. They claim that the concentration of angiotensin-converting enzyme in pregnancy-induced hypertension is too high to be the rate-limiting step in angiotensin II production. Thus there is a dilemma as to whether there is increased angiotensin II production or increased angiotensin II inactivation. In either case, an elevated angiotensin-converting enzyme level could be expected to occur. Of importance is the loss of refractoriness of arterioles in pregnant patients who have or will have pregnancy-induced hypertension. Gant et al.[11] demonstrated that increased sensitivity to angiotensin II infusion was present by 18 weeks and was the earliest indicator of subsequent pregnancy-induced hypertension. Even changes in plasma volume did not significantly affect vascular sensitivity to angiotensin II. Gant et al.[12] correlated the positive pressor response in patients with pregnancy-induced hypertension in the supine position in the third trimester (rollover test) with the sensitivity to infused angiotensin II. This had a high predictive value for the future occurrence or absence of pregnancy-induced hypertension. Lee and Todd[13] showed increased angiotensin-converting enzyme and catecholamine levels in mothers with a positive rollover test.

The rise in angiotensin-converting enzyme levels from patients with pregnancy-induced hypertension appears at about the same time that the clinical disease becomes evident. Therefore, the angiotensin-converting enzyme levels did not seem to be able to predict which patients are at risk for pregnancy-induced hypertension. However, when a patient has elevated blood pressure in pregnancy, the angiotensin-converting enzyme value is able to identify those patients with a diagnosis of pregnancy-induced hypertension. To confirm that angiotensin-converting enzyme appears to be a late or acutely occurring phenomenon, one must look at pregnant patients with chronic hypertension. In this study, these women have angiotensin-converting enzyme levels comparable to those in normotensive women, until they develop superimposed pregnancy-induced hypertension. Then the angiotensin-converting enzyme levels become elevated as are those in normal patients who develop pregnancy-induced hypertension. This correlates with the findings of Gant et al.,[14] who showed the angiotensin II refractoriness to be similar in women with chronic hypertension and normotensive women until the superimposition of pregnancy-induced hypertension. Then angiotensin II refractoriness was lost. There was no difference in an-

giotensin-converting enzyme levels according to weeks of gestation in the third trimester. This would allow diagnostic impressions to be made irrespective of gestational age. An interesting and important observation is the effect of magnesium sulfate on angiotensin-converting enzyme levels in patients with pregnancy-induced hypertension. In patients receiving magnesium sulfate, the angiotensin-converting enzyme levels were decreased to those of normotensive women and those with chronic hypertension without pregnancy-induced hypertension. This phenomenon is probably not due to plasma volume expansion as the uric acid levels and blood urea nitrogen did not demonstrate a similar decrease. In fact, patients who receive magnesium sulfate and who have more severe pregnancy-induced hypertension have uric acid levels greater than those of women not receiving magnesium sulfate ($p < 0.02$) (Fig. 4). Is this then due to an effect of magnesium sulfate on the arteriolar endothelium where angiotensin-converting enzyme is produced, or is it due to interference with the angiotensin-converting enzyme assay? The answer to this is still unknown. Elevation of uric acid has come to be an indicator of the severity of pregnancy-induced hypertension, and this progressive elevation may be indicative of poor fetal outcome.

Twin pregnancies in patients with pregnancy-induced hypertension were associated with angiotensin-converting enzyme levels that were higher (34.2 ± 6.5 units/ml) than those of singleton pregnancies with pregnancy-induced hypertension (29.1 ± 6.5 units/ml, $p < 0.05$). However, with no pregnancy-induced hypertension, the angiotensin-converting enzyme (20.5 units/ml) was similar to that in normotensive women with singleton pregnancies (21.1 ± 6.9 units/ml, p NS). The explanation does not lie with the placental size, as the total placental weights were comparable in the twin gestations with or without pregnancy-induced hypertension.

From the literature, paired samples of maternal venous and umbilical venous and arterial angiotensin-converting enzyme levels have shown that the angiotensin-converting enzyme is the same in all three spaces, that the cord venous levels are greater than cord arterial or maternal venous levels, or that the umbilical venous angiotensin-converting enzyme concentration is less than that in maternal venous blood.[2] In our study (Table II), the values suggest that the maternal venous value is less than the cord venous value and greater than the cord arterial value. The question remains if these differences are real. An additional source of angiotensin-converting enzyme in pregnancy may well be the placenta,[15] with distribution to both maternal and fetal circulations. The amniotic fluid levels are significantly less than in the other compartments (<5 units/ml) and, therefore, are probably of little significance.

An increased angiotensin-converting enzyme concentration is not exclusive to pregnancy-induced hypertension. Angiotensin-converting enzyme is shown to be elevated in sarcoid, thyroid disease, and in neonates with respiratory distress syndrome, and we now have one patient with systemic lupus erythematosus at 8 weeks' gestation, with normal blood pressure, whose angiotensin-converting enzyme level is 34.8 units/ml. Lieberman and Sastre[16] reported elevated angiotensin-converting enzyme levels in diabetic patients, but our experience shows variable values that do not seem to be predictive of whether the patient has pregnancy-induced hypertension. Observation of mean arterial blood pressure (Fig. 3) before 20 and after 24 weeks in normotensive gestations demonstrated a rise in the third trimester of pregnancy. This may well correspond with the mild decrease and plateau in angiotensin II refractoriness shown by Gant et al.[3] The mean arterial blood pressure in patients with pregnancy-induced hypertension and chronic hypertension with or without superimposed pregnancy-induced hypertension followed expected patterns.

The theoretical interrelationships of the components that control blood pressure in normal pregnancy and those complicated by pregnancy-induced hypertension–preeclampsia are seen in Fig. 5. The renin-angiotensin system seems to be well established. Estrogen may drive the system by increasing angiotensinogen substrate, as pregnancy is associated with increased maternal-placental estrogen levels. Although angiotensin-converting enzyme is predominantly found in the lung[15] and is the usual site of conversion for angiotensin I to angiotensin II, in pregnancy, the placenta[15] may play an important and additional role in this system. Normally the increased substrate may lead to increased angiotensin II but progressive increases in angiotensinase[4] protect the mother from the angiotensin II. Bradykinin, a potent vasodilator, sits in balance with angiotensin II. It is a competitive inhibitor of angiotensin I conversion, and bradykinin-potentiating factors inhibit the destruction of bradykinin and block the conversion of angiotensin I to angiotensin II. However, bradykinin is inactivated in the lungs, which suggests that angiotensin-converting enzyme may well promote this inactivation of bradykinin or blocking of bradykinin-potentiating factors. An imbalance in this system may then explain the increased sensitivity of the arterioles to angiotensin II and the clinical presentation of pregnancy-induced hypertension. The linkage of this system to the prostaglandins was provided by the facts that indomethacin, a prostaglandin synthetase inhibitor, decreased the refractoriness to angiotensin II in normal pregnant women, that infusions of prostaglandin E_2 lower angiotensin II sensitivity, and that prostaglandin I_2 (prostacyclin) was responsible for va-

sodilation, decreased platelet adhesiveness, and prevention of fibrin deposition. Prostaglandin I_2 was found to be decreased in pregnancies associated with pregnancy-induced hypertension, leaving a relative imbalance with increased thromboxane A_2. Thromboxane A_2 is released from the platelets and is responsible for vasoconstriction, platelet adhesiveness, and fibrin deposition. Thus Page's "inner vicious circle"[1] of decreased uterine placental perfusion associated with vasoconstriction, damage to the placenta, thromboplastin release, intravascular coagulopathy, fibrin deposition in the kidney, decreased glomerular filtration rate, sodium and water retention, and intracellular shift of sodium to increase vascular sensitivity to pressors explains the clinical situation of pregnancy-induced hypertension. However, the critical piece in this puzzle is the finding that bradykinin has control over the production of prostaglandin E and prostaglandin I_2 and bridges the gap between the renin-angiotensin system and the prostaglandins in the physiologic control mechanisms of pregnancy-induced hypertension. Angiotensin-converting enzyme, by its role in conversion of angiotensin I to angiotensin II and the inactivation of bradykinin, may be partially responsible for the decrease in prostaglandin E and prostaglandin I_2 in pregnancy-induced hypertension–preeclampsia.

The current study has shown significant relationships of angiotensin-converting enzyme to the clinical pictures of pregnancy-induced hypertension that occur in previously normotensive and chronically hypertensive pregnant women. Simultaneous measurements of several of the components of the systems controlling vascular reactivity are required and may confirm the now theoretical mechanisms responsible for the maintenance of normal blood pressure in normal pregnancy or the occurrence of elevated blood pressure in pregnancy-induced hypertension–preeclampsia.

Discussion

DR. NORMAN GANT, Dallas, Texas. I thoroughly enjoyed reading the paper by Goldkrand and Fuentes. The authors observed that the angiotensin-converting enzyme was elevated in patients with pregnancy-induced hypertension when compared with normotensive pregnant women or pregnant women with uncomplicated chronic hypertension. In fact, the serum levels of angiotensin-converting enzyme were elevated in patients with pregnancy-induced hypertension to values essentially the same as observed in nonpregnant subjects.

The authors also observed that the angiotensin-converting enzyme levels were reduced to normal levels in the third trimester of pregnancy in women with pregnancy-induced hypertension who were treated with magnesium sulfate. The authors then compared these serum angiotensin-converting enzyme values to mean arterial blood pressures as well as blood urea nitrogen and uric acid values obtained in the same patients. As one might expect, uric acid and blood urea nitrogen levels were elevated in patients with pregnancy-induced hypertension whether or not they were treated with magnesium sulfate.

The authors also simultaneously measured serum angiotensin-converting enzyme values in women and in the cord blood of their infants. Unfortunately, there were not enough values to draw any firm conclusions from this portion of the study nor were there enough

values obtained in patients with diabetes to draw any firm conclusions.

The authors discussed their observations and proposed an interesting hypothesis that angiotensin-converting enzyme might be involved in the suppression of bradykinin. This in turn might result in a decreased production of prostacyclin and prostaglandin E_2 in vascular endothelium resulting in the increased sensitivity to angiotensin II that precedes the onset of pregnancy-induced hypertension. I found this hypothesis fascinating and an idea that needs to be investigated. I have several questions, however, concerning the present study before I am willing to accept the role of angiotensin-converting enzyme in the proposed hypothesis.

The results reported for angiotensin-converting enzyme in the present study were reported as units per milliliter. Because these values were not reported as specific activities, it is entirely possible that what the authors are observing in this study is a constriction in plasma volume resulting in an artificial elevation of angiotensin-converting enzyme levels in women with pregnancy-induced hypertension. They mention this but do not elaborate on this possibility. I believe it is imperative that this issue be resolved.

The observation that magnesium sulfate lowers angiotensin-converting enzyme values to normal levels in patients with pregnancy-induced hypertension is interesting and may well be, as suggested by the authors, the result of magnesium sulfate acting directly on endothelium to increase the production of angiotensin-converting enzyme. Certainly there is a recent report that magnesium sulfate stimulates vasodilation and an increase in prostacyclin in the human umbilical cord (Altura et al., Science 1983;221:376). It also may be that magnesium sulfate has a similar affect by increasing the angiotensin-converting enzyme production as well as prostacyclin production in vascular endothelium. If so, this would be a valuable piece of information that would be yet another reason for using magnesium sulfate to arrest and prevent seizures in patients with pregnancy-induced hypertension as well as to increase tissue perfusion in the mother as well as the fetus.

The authors also acknowledge that magnesium sulfate might interfere with the assay of angiotensin-converting enzyme. It is a very simple matter to ascertain if this is a possibility by simply adding magnesium sulfate to serum obtained from untreated preeclamptic women and then running the assay. In this way one would have eliminated the endothelium as a possible source of angiotensin-converting enzyme and could in a very short period of time ascertain whether the magnesium sulfate is merely interfering with the assay.

In closing, let me say that the authors should be congratulated for a carefully conducted clinical study. Their review of the literature and their hypothesis for a mechanism to explain their observations were well done. I urge them to resolve, as soon as possible, the questions that I have raised concerning what may very well be an extremely important observation in our continuing search for a cause of pregnancy-induced hypertension.

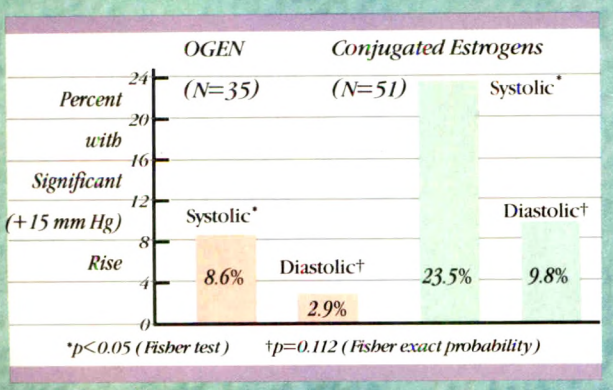
DR. GOLDKRAND (Closing). First I would like to thank Dr. Gant for his kind remarks and for preparing for us the next stage in our investigation.

I would also like to take this opportunity to thank my coinvestigator, Dr. Fuentes, who was really one of the prime movers in this project and I think deserves credit for his work.

In relation to the comments that Dr. Gant made, I think they are very important as to whether we are seeing an effect that is due to constriction of blood volume. However, we have not yet looked at other factors. The suggestion of using Evans blue dye to evaluate the supposition that this may be a blood volume phenomenon raises a real question. The fact is that the change in angiotensin-converting enzyme does not occur early. It is a late-occurring phenomenon.

If the sample for measurement of angiotensin-converting enzyme is drawn early, it does not really have predictive value. Differential diagnosis is possible in the patient who presents with hypertension, but there may be an abnormality of the elevated enzyme. Dr. Gant's comments may be true and have yet to be elucidated.

The effect of magnesium sulfate is certainly one that needs to be evaluated very soon. We have also wondered about this effect. With our use of Swan-Ganz catheters in some of our extremely ill patients, we have not really seen a major change in some of the factors that might accompany the production of prostacyclin and block the potential action of angiotensin-converting enzyme.



Part of the problem is that the true half-life of this enzyme is not known because it has not been well worked out, and the effects that may be taking place from a therapeutic modality may not immediately demonstrate any change. At other times, when using other treatment modalities for a longer time, we do see changes both in blood volume and in stabilization of patients, so there may be a time factor here that needs to be evaluated.

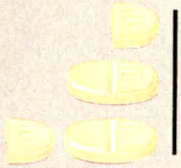
However, the effect of magnesium sulfate on the assay is certainly a question that is begged very strongly and is about to be answered in the laboratory by the addition of magnesium sulfate to the blood sample to see if it has a direct effect on the assay method.

Her estrogen therapy shouldn't affect her blood pressure

Percent of patients showing BP change of 15 mm Hg or greater after 7.4 months to 7.9 months therapy with either conjugated estrogens or OGEN® (estropipate)

Adapted from Wren et al, 1981.[1]

OGEN dosages ranged from 0.625 to 2.5 daily, 24 out of 30 days. Conjugated estrogen dosages ranged from 0.3 to 2.5, 24 out of 30 days. The majority of those experiencing a change, like the majority of the total sample, were also taking a progestogen, levonorgestrel 0.03 mg, from the 15th to the 24th day.

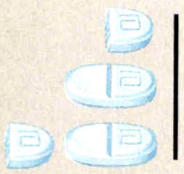


Because the risk of hypertension increases with age, it is appropriate to examine the effects of estrogen replacement on blood pressure.

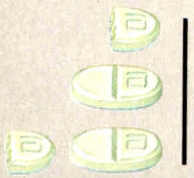
"More women receiving...[conjugated estrogens] had a clinically significant rise in blood pressure than those receiving Ogen..."[1]

OGEN®
(estropipate)

Only estrone. Identical to the body's own.



Scored tablets make precise dosing easy



OGEN .625
(estropipate 0.75 mg, calculated as sodium estrone sulfate 0.625 mg)

OGEN 1.25
(estropipate 1.5 mg, calculated as sodium estrone sulfate 1.25 mg)

OGEN 2.5
(estropipate 3 mg, calculated as sodium estrone sulfate 2.5 mg)

OGEN 5
(estropipate 6 mg, calculated as sodium estrone sulfate 5 mg)

OGEN tablets are scored so you can adjust dosage without writing a new prescription. It's another reason more physicians are prescribing OGEN.

OGEN®
(estropipate)

Only estrone. Identical to the body's own.

See adjacent page for brief summary of prescribing information.

ESTROPIPATE TABLETS, USP

Tablets

WARNING:

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prucent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. OGEN SHOULD NOT BE USED DURING PREGNANCY.

According to some investigators, the use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. Studies have reported that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. In one of these studies, this risk was estimated as not greater than 4 per 1000 exposures. Furthermore, there are reports that a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these reported changes are histologically benign, the investigators have not determined whether they are precursors of adenocarcinoma.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies in the offspring, including heart defects and limb reduction defects. One case control study estimated a 4.7 fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. OGEN has not been studied for these uses, and therefore should not be used during pregnancy. There is no evidence from well controlled studies that progestogens are effective for these uses.

If OGEN (estropipate tablets) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the question of continuation of the pregnancy should be addressed.

INDICATIONS AND USAGE

The cyclic administration (See "DOSAGE AND ADMINISTRATION" section) of OGEN (estropipate tablets) is indicated for the treatment of estrogen deficiency associated with:

1. Moderate to severe *vasomotor* symptoms of menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.

OGEN (ESTROPIPATE TABLETS) HAS NOT BEEN TESTED FOR EFFICACY FOR ANY PURPOSE DURING PREGNANCY. SINCE ITS EFFECT UPON THE FETUS IS UNKNOWN, IT CANNOT BE RECOMMENDED FOR ANY CONDITION DURING PREGNANCY (SEE BOXED WARNING).

CONTRAINDICATIONS

OGEN should not be used in women with any of the following conditions:

1. Known or suspected cancer of the breast.
2. Known or suspected estrogen-dependent neoplasia.
3. OGEN may cause fetal harm when administered to a pregnant woman. OGEN is contraindicated in women who are or may become pregnant (See Boxed Warning).
4. Undiagnosed abnormal genital bleeding.
5. Active thrombophlebitis or thromboembolic disorders.
6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. *Induction of malignant neoplasms.* Long-term continuous administration of natural and synthetic estrogens in certain animal species has been reported by some investigators to increase the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning).

At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. Therefore, caution should be exercised when administering estrogens to women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. Careful breast examinations should be performed periodically.

2. *Gall bladder disease.* A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use.

3. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat postpartum breast engorgement would be more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in women receiving estrogens for postpartum breast engorgement.

a. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism; it should also be discontinued during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. *Hepatic adenoma.* Benign hepatic adenomas appear to be associated with the use of oral contraceptives. Although benign, and rare, these may rupture and cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time.

c. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used.

d. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

PRECAUTIONS

A. General Precautions.

1. A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Fluid retention — Estrogens may cause some degree of fluid retention. Therefore, patients with conditions such as epilepsy, migraine, and cardiac or renal dysfunction, which might be influenced by this factor, require careful observation.
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc.
4. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
5. Preexisting uterine leiomyomata may increase in size during estrogen use.
6. The pathologist should be advised of the patient's use of estrogen therapy when relevant specimens are submitted.
7. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients.
9. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency.

B. Information for the Patient. See text of Patient Package Insert which appears after PHYSICIAN REFERENCES.

C. Drug Interactions. The concomitant use of any drugs which can induce hepatic microsomal enzymes with estrogens may produce estrogen levels which are lower than would be expected from the dose of estrogen administered.

The use of *broad spectrum antibiotics* which profoundly effect intestinal flora may influence the absorption of steroidal compounds including the estrogens.

Diabetics receiving *insulin* may have increased insulin requirements when receiving estrogens.

Laboratory Test Interference. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Abnormal glucose tolerance test results.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

D. Carcinogenesis. Studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods (see Boxed Warning). At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. (See "WARNINGS" section.)

E. Pregnancy. Pregnancy Category X. See "CONTRAINDICATIONS" section and Boxed Warning.

F. Nursing Mothers. Estrogens have been reported to be excreted in human breast milk. Caution should be exercised when OGEN is administered to a nursing woman.

G. Pediatric Use. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete.

ADVERSE REACTIONS

(See Warnings regarding reports of possible induction of neoplasia, unknown effects upon the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions in decreasing order of severity within each category have been reported with estrogenic therapy, including oral contraceptives:

1. *Genitourinary system.*
   Increase in size of uterine fibromyomata.
   Vaginal candidiasis.
   Cystitis-like syndrome.
   Dysmenorrhea.
   Amenorrhea during and after treatment.
   Change in cervical eversion and in degree of cervical secretion.
   Breakthrough bleeding, spotting, change in menstrual flow.
   Premenstrual-like syndrome.
2. *Breast.*
   Tenderness, enlargement, secretion.
3. *Gastrointestinal.*
   Cholestatic jaundice.
   Vomiting, nausea.
   Abdominal cramps, bloating.
4. *Skin.*
   Hemorrhagic eruption.
   Erythema nodosum.
   Erythema multiforme.
   Hirsutism.
   Chloasma or melasma which may persist when drug is discontinued.
   Loss of scalp hair.
5. *Eyes.*
   Steepening of corneal curvature.
   Intolerance to contact lenses.
6. *CNS.*
   Chorea.
   Mental depression.
   Migraine, dizziness, headache.
7. *Miscellaneous.*
   Aggravation of porphyria.
   Edema.
   Reduced carbohydrate tolerance.
   Increase or decrease in weight.
   Changes in libido.

OVERDOSAGE

Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION

1. *Given cyclically for short-term use:*

For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., 3 weeks on and 1 week off).

Attempts to discontinue or taper medication should be made at 3 to 6 month intervals.

Usual dosage ranges:

Vasomotor symptoms —One OGEN .625 Tablet to one OGEN 5 Tablet per day. The lowest dose that will control symptoms should be chosen. If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding.

Atrophic vaginitis and kraurosis vulvae — One OGEN .625 Tablet to one OGEN 5 Tablet daily, depending upon the tissue response of the individual patient. The lowest dose that will control symptoms should be chosen. Administer cyclically.

2. *Given cyclically:*

Female hypogonadism; female castration; primary ovarian failure.

Usual dosage ranges:

Female hypogonadism — A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. The lowest dose that will control symptoms should be chosen. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium. If satisfactory withdrawal bleeding does not occur, an oral progestogen may be given in addition to estrogen during the third week of the cycle.

Female castration and primary ovarian failure —A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED

OGEN (estropipate tablets, USP) is supplied as OGEN .625 (0.75 mg estropipate), yellow tablets, **NDC** 0074-3943-04; OGEN 1.25 (1.5 mg estropipate), peach-colored tablets, **NDC** 0074-3946-04; OGEN 2.5 (3 mg estropipate), blue tablets, **NDC** 0074-3951-04; and OGEN 5 (6 mg estropipate), light green tablets, **NDC** 0074-3958-13. Tablets of all four dosage levels are standardized to provide uniform estrone activity and are grooved (Divide-Tab®) to provide dosage flexibility. All tablet sizes of OGEN are available in bottles of 100.

Incorporation of labeled ribonucleic acid precursors into maternal and fetal rat tissues during pregnancy

Mary Ellen Dorko, B.S., and T. Terry Hayashi, M.D.
Pittsburgh, Pennsylvania

Tritium-labeled ribonucleic acid precursors, including cytidine, uridine, and orotic acid, were injected into rats with dated pregnancies (14 to 21 days) and virgin rats. The acid-insoluble counts indicating incorporation into fetal and placental tissues showed that the highest incorporation occurred with cytidine, particularly earlier in pregnancy. In contrast, uridine demonstrated a minor degree of incorporation but displayed facile and enhanced transplacental passage with duration of pregnancy as represented by acid-soluble counts. Orotic acid was minimally used by both fetal and placental tissues. The incorporation of labeled precursors into maternal liver, heart, and kidney demonstrated varying responses during the course of pregnancy. (AM J OBSTET GYNECOL 1986;154:801-5.)

Key words: Tritium-labeled ribonucleic acid precursors, pregnant rats, fetal and placental ribonucleic acid incorporation

The incorporation of various ribonucleic acid (RNA) precursors into fetal and maternal tissues differs under various conditions.[1-4] There is enhanced incorporation of cytidine in comparison with uridine and orotic acid by the maternal rat liver,[5] and RNA metabolism in the maternal liver changes in accordance with fetal nutritional demands at various gestational ages.[5] Our previous studies demonstrated enhanced transplacental passage of uridine during late pregnancy.[1] The present study includes experiments with uridine, orotic acid, and cytidine during the last trimester of pregnancy in rats. The study was designed to assess transplacental passage and placental and fetal incorporation of cytidine, uridine, and orotic acid. We also took advantage of the labeled animals to study changes in RNA metabolism in maternal liver, heart, and kidney during pregnancy. In the current study the labeled precursors were administered intravenously rather than intraperitoneally as in previous reports.

Material and methods

Sprague-Dawley rats (Zivic-Miller, Allison Park, Pennsylvania) fed ad libitum included dated, pregnant rats and virgin rats. Labeled precursors were (5-^{3}H) cytidine (23 Ci/mmol), (5-^{3}H) uridine (20 Ci/mmol), and (5-^{3}H) orotic acid (21 Ci/mmol). Under light anesthesia with methoxyflurane, isotonic saline suspensions of labeled precursors (10 μCi/100 gm body weight) were injected into the saphenous vein with a beveled (25-gauge, ½-inch) needle. After 120 minutes, 3 ml of blood was removed by cardiac puncture, the animals were killed by cervical dislocation, and the various tissues were resected. The minimum number of rats in each group was five.

The 2-hour pulse labeling time was selected based on earlier studies indicating that the maximum incorporation of the three precursors had occurred during the first 2 hours after intravenous injection,[1] although orotic acid did continue to be incorporated slowly for hours.

Preparation and treatment of tissue extracts. The 3.0 ml cardiac tap blood sample was centrifuged at 10,000 × g for 15 minutes. A 0.1 ml aliquot of the serum was placed in a scintillation vial with 10.0 ml of 3a70B cocktail (Research Products International Corporation, Mt. Prospect, Illinois) and assayed for radioactivity.

The various tissues were minced, suspended in nine volumes of cold 0.1 mol/L sodium acetate buffer, pH 5.0, and homogenized with 10 strokes with a Potter-Elvehjem Teflon-pestle tissue grinder (Thomas Scientific, Swedesboro, New Jersey). A one tenth volume of 50% cold trichloroacetic acid was added to the homogenate, incubated on ice for 20 minutes, and centrifuged at 10,000 × g for 10 minutes. The resulting acid-soluble supernate was removed and the precipitate washed twice with cold 5% trichloroacetic acid. A 0.5 ml aliquot of the pooled supernate and washings was placed in 10.0 ml of 3a70B, and the acid-soluble radioactivity measured in a Packard Tri-Carb liquid scintillation system (Packard Instrument Co., Inc., Downers Grove, Illinois).

To the precipitate, 5.0 ml of 10% trichloroacetic acid was added and the mixture heated at 100° C for 15 min-

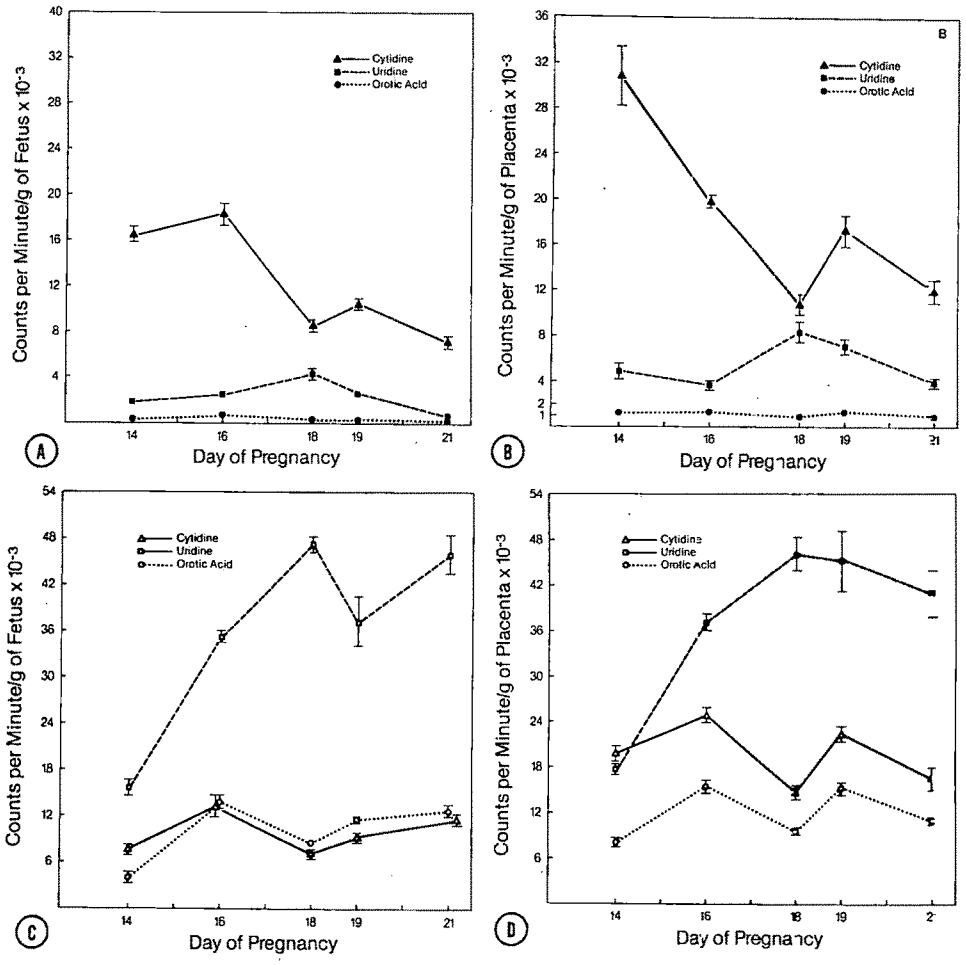

Fig. 1. Comparison of tritium-labeled cytidine, tritium-labeled uridine, and tritium-labeled orotic acid incorporation into fetal and placental tissues 2 hours after injection. RNA precursor radioactivity is measured in acid-insoluble counts (*A*, fetus; *B*, placenta) and acid-soluble counts (*C*, fetus; *D*, placenta). Each point represents five to 10 determinations (mean ± SEM).

utes. After cooling and centrifuging the sample, 0.5 ml aliquots of the acid-insoluble solution were assayed for radioactivity. All procedures were carried out at 4° C.

Results

The acid-insoluble counts per gram of tissue, which indicate the amount of precursors incorporated into the tissue, clearly showed that the greatest incorporation into both the fetal and placental tissues occurred with tritium-labeled cytidine (Fig. 1, *A* and *B*). The placenta showed approximately twice the amount of incorporation compared to the fetus. Although the total amount of radioactivity incorporated into both fetuses and placentas increased with the duration of pregnancy because of rapidly increased total weight and size, the greater amount of radioactivity per unit mass of tissue was measured in the earlier stages of pregnancy. The degree of incorporation with uridine and orotic acid was minimal. There was a marginal decrease in cytidine incorporation and slightly increased incorporation of uridine in the rats with pregnancies of 18 days.

The acid-soluble counts per gram of tissue, representing the amount of precursors taken up by tissue but not incorporated (Fig. 1, *C* and *D*), indicated enhanced placental and fetal transfer of uridine with increasing duration of pregnancy. Orotic acid showed minimal and consistent levels of placental and fetal transfer during pregnancy.

The incorporation of RNA precursors into maternal tissues varied with the organ involved (Fig. 2, *A*, *B*, and *C*). In the maternal liver (Fig. 2, *A*), both cytidine and orotic acid had depressed incorporation initially in early pregnancy but later increased to reach nonpregnant levels near term. There was minuscule incorporation of labeled uridine. The adult heart (Fig. 2, *B*) demonstrated the highest incorporation with cytidine but the degree of incorporation was decreased twofold during pregnancy. Uridine and orotic acid had minimal incorporation throughout the study. The maternal kid-

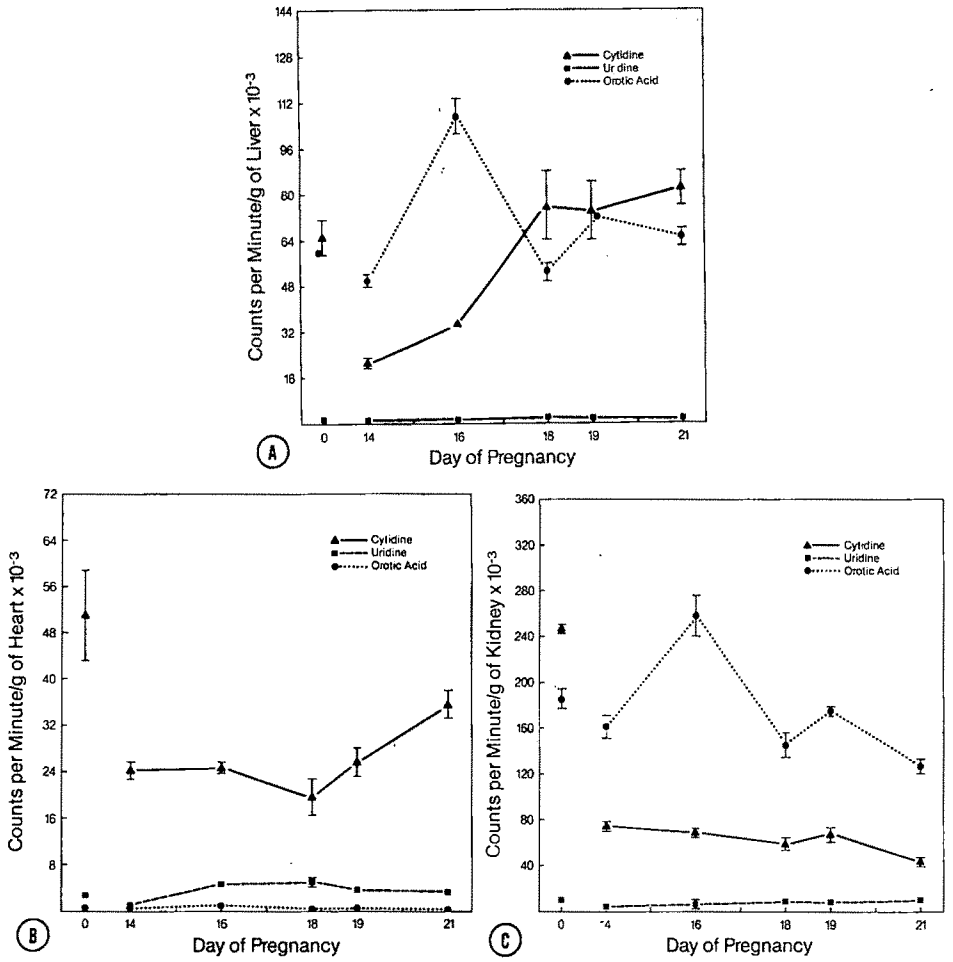

Fig. 2. Comparison of tritium-labeled cytidine, tritium-labeled uridine, and tritium-labeled orotic acid incorporation into maternal liver *(A)*, maternal heart *(B)*, and maternal kidney *(C)* 2 hours after injection. RNA precursor radioactivity measured in acid-insoluble counts, each point representing five to 10 determinations (mean ± SEM).

ney (Fig. 2, *C*) revealed the most unusual changes with pregnancy. In the nonpregnant state cytidine exhibited the highest incorporation, but during pregnancy orotic acid incorporation exceeded that of cytidine by twofold to threefold. However, as the duration of pregnancy increased, the incorporation of both orotic acid and cytidine declined. Again, there was only slight incorporation of uridine.

The cardiac tap serum consistently revealed the following radioactivity levels during pregnant and nonpregnant states: uridine, 54,000 to 90,000 cpm ml^{-1}; orotic acid, 21,000 to 26,000 cpm ml^{-1}; and cytidine, 11,000 to 14,000 cpm ml^{-1}.

Comment

The present study clearly indicates that of the three RNA precursors, cytidine is used most efficiently in the biosynthesis of placental and fetal RNA during the second half of pregnancy. This was somewhat unexpected since orotic acid is incorporated into RNA along the pathway of de novo synthesis while cytidine and uridine are incorporated along the salvage pathways. The enhanced incorporation of cytidine occurred in spite of facile placental transfer of uridine and raises the question of the absence of uridine kinase in fetal and placental tissue. Whether cytidine is used so effectively in the earlier stages of pregnancy remains to be examined. Such microsurgical studies are contemplated since early gestational experiments will have important implications for the study of teratogenesis and embryonic growth. It is interesting to note the marked mutagenic effect of a cytidine derivative in a microbial system.[7] The current gestational period that was studied, however, may provide appropriate background for the study of intrauterine growth retardation in a rat model being developed in this laboratory.

In a previous report Larkin and Stevens[6] demonstrated significant incorporation of tritium-labeled cytidine into both deoxyribonucleic acid (DNA) and RNA in 12-day pregnant rats especially in the junctional zone

of the placenta. The amount of DNA was not cited. Our future studies will include the use of carbon 14–labeled cytidine with alkaline hydrolysis used to determine the ratio of RNA/DNA labeling in both the fetus and placenta during the course of pregnancy. In addition, other studies will determine whether labeled cytidine is incorporated as such or as uridine.

The rapid and facile transfer of uridine to both fetus and placenta was surprising because the incorporation of uridine is so low. Additional short-pulse labeling experiments conducted at 15-minute intervals for 2 hours confirmed that uridine is indeed transferred rapidly and not used. There was no evidence of increased breakdown of uridine as suggested previously by Larkin and Stevens.[6] Future studies are planned to determine whether the bulk of acid-soluble uridine radioactivity remains as a nucleoside and is not phosphorylated. Uridine phosphorylase activity has been reported in adult rat blood.[8] In an earlier report we demonstrated the incorporation of ^{14}C-labeled uridine into fetal and placental uridine monophosphate in near-term pregnant rats.[1] The results noted in the 14-day pregnant rat (Fig. 1, *C* and *D*) suggest that the facile transfer of uridine may not extend to earlier stages of pregnancy.

In the nonpregnant state, both orotic acid and cytidine have been reported to be used much more than uridine for RNA synthesis in the rat liver.[9, 10] It is interesting that, in a recent report, Lewan et al.[11] demonstrated that in the male mouse the incorporation of tritium-labeled cytidine was two to three times greater than that of labeled uridine or orotic acid. Thus there are important species differences to consider as well as metabolic and hormonal influences. In our present study the incorporation of cytidine and orotic acid increased in the maternal liver during pregnancy to exceed nonpregnant values (Fig. 2, *A*). Simultaneously, the incorporation of cytidine decreased in both the fetus and the placenta. The changes may reflect either an increase in maternal liver RNA synthesis to provide nutrients for the enlarging fetoplacental unit or an enhanced ability of a mature fetoplacental unit to synthesize RNA precursors de novo, thereby decreasing the need for a large maternal supply.

The only significant incorporation in the maternal heart occurred with cytidine. The twofold decrease in cytidine incorporation with pregnancy may have resulted from the increased use of cytidine by the fetus and placenta or from increased circulatory demands in the maternal system. There was a modest increase in cytidine incorporation near term.

In the maternal kidney there was a striking threefold decrease in cytidine incorporation with pregnancy, which may have resulted entirely from the enhanced fetal and placental use. Orotic acid, which is not used in a similar fashion, demonstrated fairly constant incorporation in both pregnant and nonpregnant states. In contrast to the other two maternal organs, the incorporation of orotic acid and cytidine decreased near term, suggesting that the control of RNA synthesis in the kidney during pregnancy differs from that in the liver and heart.

The use of a beveled 25-gauge needle enabled us to inject the labeled precursors intravenously with consistency, thereby avoiding any accidental intra-amniotic injection, especially near term. There was no increase in the values of SD (not shown) and SEM of the measured radioactivity in the fetus and placenta in late pregnancy. Furthermore, the consistent values observed in the cardiac taps throughout the entire study, including pregnant and nonpregnant states, additionally reaffirmed the efficacy of the intravenous route. Our previous studies indicating fetal incorporation of uridine may have resulted from intra-amniotic injection of the isotope.[1] Greenman[12] has compared the use of subcutaneous and intraperitoneal injection of uridine in nonpregnant rats.

In summary, the present study demonstrated enhanced use of cytidine by the fetus and placenta, although there was a facile and rapid transfer of uridine to the fetoplacental unit. Studies performed with the maternal organs indicated that there are differences in the incorporation of RNA precursors among the various maternal organs during the different stages of pregnancy.

Discussion

Dr. Sergio E. Fabro, Washington, D. C. The authors present data from experiments in which pregnant rats were treated intravenously with tritiated cytidine, uridine, or orotic acid at different stages of pregnancy. Two hours after dosing the animals were put to death and the tritium activity was measured in the acid-insoluble and acid-soluble fractions of homogenates of fetal and maternal tissues. After the administration of radioactive cytidine to rats at 14 days of pregnancy, the acid-insoluble fraction of fetal and placental samples contained significantly more radioactivity than the corresponding tissues in parallel experiments with radioactive uridine and orotic acid. Furthermore, whereas low levels of tritium incorporation into the acid-insoluble fraction of the fetus and placenta were consistently noted after uridine and orotic acid administration to rats at 16, 18, 19, and 20 days of pregnancy, the corresponding experiment with cytidine showed a decrease in tritium incorporation into the insoluble fraction that was approximately inversely related to the gestational age.

On the other hand, the acid-soluble counts showed similar results at different gestational ages for uridine and orotic acid. In the experiments with cytidine, however, the amount of radioactivity in the fetal and placental compartments increased as pregnancy progressed.

These experiments are the logical extension of earlier work by the same group, in which the relationship between maternal pharmacodynamics, placental permeability, and nucleic acid biosynthesis in the fetoplacental unit have been the subject of study; past contributions by this group have been significant in improving our understanding in these areas. This type of experiment, attempting to clarify placental permeability as well as fetal macromolecular synthesis at different gestational ages, is important since our knowledge in this area is meager at best. However, the data as presented today require additional information to be truly informative. In performing experiments with radioactive compounds, it is nowadays essential to identify the chemical entity that the radioactivity represents. As mentioned in the Comment section, the authors plan to carry out future experiments that will lead to the identification of the radioactivity. Thus a first step for understanding the significance of the amount of radioactivity found in fetal and placental tissues at different gestational ages would be the chemical identification of such radioactivity. In this regard, if one wants to be picky, he or she would ask an important initial question: How did the authors check the purity and radiostability of the tritium in the compounds used?

In terms of pharmacokinetics, why did the authors select 2 hours after treatment as a one-time examination for all three chemicals at different stages of pregnancy? The other difficulty I have in dealing with the data presented is related to the pool size of the radioactive chemicals in the specific maternal, fetal, and placental compartments. Thus the data as presented today can be interpreted only on the assumption that the pool sizes of the administered chemicals are equal and remain constant at different stages of pregnancy. This is an assumption that may not be correct.

In summary, I think it would add significantly to the scientific value of the study if the authors would identify the radioactivity and determine the actual pool size of the different precursors that were used in the various fetoplacental compartments at different gestational ages. It is a lot of work, but it will increase the scientific value of these data considerably.

Dr. Hayashi (Closing). I thought somebody was going to ask me the question: Why are you doing this experiment? Actually, we have developed a rat animal model for intrauterine growth retardation, and I wanted to find out the fetoplacental metabolism of that model. That is the reason we chose this approach.

Dr. Fabro's first question regarding the biochemical identification is critical for our future study, especially with the uridine radioactivity being so high. If I had to guess, the radioactivity represents uracil, which would explain everything because otherwise we are dealing with a brand new eukaryotype of uridine kinase.

Two hours was chosen, Dr. Fabro, because our previous studies during the course of pregnancy showed that maximum incorporation took place within 2 hours. I appreciate that for pharmacokinetics we should do more extensive studies.

In one of our previous studies we did measure pool size. I have one problem with just measuring the RNA pool size, because in a report by Larkin and Stevens (see reference 6) they have reported the incorporation of cytidine into DNA. They did not specify quantity, but they observed DNA especially in the junctional zone of the placenta. Thus in the early part of pregnancy, we may be seeing a higher DNA ratio, so alkaline hydrolysis may have to be performed to measure the DNA/RNA ratio. Furthermore, we may have to do phenolextraction of RNA to be sure about the exact RNA pool size. We have raised additional questions with the present study.

Uterine artery Doppler velocimetry in pregnant women with hypertension

Adiel Fleischer, M.D., Harold Schulman, M.D., George Farmakides, M.D., Luis Bracero, M.D., Lawrence Grunfeld, M.D., Burton Rochelson, M.D., and Mordecai Koenigsberg, M.D.

Stony Brook, New York

Uterine and umbilical artery velocimetry was carried out on 71 women with hypertensive disorders in pregnancy. Three categories of hypertensive disease were diagnosed: chronic hypertension, preeclampsia, and chronic hypertension with superimposed preeclampsia. Clinical classifications describe the severity of disease effectively, primarily because the classification is based on the appearance of abnormal physical or laboratory findings. Doppler velocimetry of the uterine arteries shows that normal pregnancy occurs when the systolic/diastolic ratio is ≤2.6. When the ratio exceeds this level and there is a notch in the waveform, the pregnancy is complicated by stillbirth, premature birth, intrauterine growth retardation, and maternal preeclampsia. The positive and negative predictive value of the examination is 93% and 91%, respectively. It appears that this new technology will be an essential ingredient of optimum pregnancy surveillance. (AM J OBSTET GYNECOL 1986;154:806-13.)

Key words: Doppler, ultrasound, uterine arteries, hypertension, pregnancy

The diagnosis and management of hypertension in pregnancy have been handicapped by the absence of a precise test that will separate chronic hypertension from preeclampsia.[1,2] A combination of historical, clinical, and laboratory factors are used to make a diagnosis and to formulate a plan of management.[3-5] Since a precise diagnosis is not possible, clinical decisions to induce labor or carry out a cesarean section are based on probability estimates and therefore are subject to error. It is also recognized that the majority of women with chronic hypertension will not develop superimposed preeclampsia, but an extensive surveillance process is recommended because of our diagnostic deficiencies. Concepts such as calculation of the mean arterial pressure, the "rollover test," and the angiotension infusion test have been introduced as an effort to identify early disease and develop treatment plans.[6,7] However, the sensitivity of these tests has been too low to attract widespread clinical usage.

Doppler arterial velocimetry provides a new noninvasive approach to the study and evaluation of the umbilical and uterine arteries.[8-11] In previous reports we described the value of umbilical velocimetry in normal fetal growth, intrauterine growth retardation, and discordant twin pregnancies. In this report we will present data that will demonstrate the power of this new technology in accurately identifying the status of the uteroplacental circulation in the presence of maternal hypertension. It will be shown that the presence or absence of the development of uterine artery compliance has a significant impact on the perinatal outcome and the degree of maternal systemic disease.

Winthrop-University Hospital (formerly Nassau Hospital) during 1982 to 1984. The project was approved by the Institutional Committee on Human Investigation, and informed consent was obtained. The equipment used to obtain the arterial velocity waveform was a continuous-wave Doppler with a 4 MHz transducer and a power density of 6.5 mW/cm^2. A description of the equipment and the methodology has been published previously.[8] An attempt was made to obtain both umbilical and uterine velocity waveforms in each patient admitted to the study. The umbilical waveforms were obtained transabdominally with the patient in the left or right lateral tilt supine position. The systolic/diastolic ratio was used to quantitate these waveforms.

The uterine velocity waveforms were obtained vaginally or abdominally. In the early phase of these studies we thought that studies carried out through the vagina would provide easier access and more reliable uterine artery signals. This proved not to be generally true, and the vaginal approach was more uncomfortable. For the vaginal studies the transducer is placed into a sterile glove with coupling jelly and then introduced into the lateral vaginal fornix along the paracervical area. The pregnant uterine artery waveform has a specific contour and can be easily differentiated from the external iliac arteries (Fig. 1).

The abdominal studies were carried out by placing the transducer on the anterior abdominal wall in the right and left lower quadrants aimed into the lower uterine segment and gently moved around until the appropriate velocity waveforms were seen. A total of 59 women had vaginal studies, and 12 women had the waveforms obtained transabdominally. Our data on normal pregnant women have shown that the vaginal and abdominal systolic/diastolic ratios were identical after 26 weeks. Calculations represent the average value between the right and left uterine artery.

At the end of pregnancy these 71 women were then grouped into three categories based on clinical criteria, that is, chronic hypertension, preeclampsia, and chronic hypertension with superimposed preeclampsia. Patients with preexistent hypertension or second-trimester mean arterial pressures of 90 mm Hg were identified as being chronically hypertensive.[12] Those with an increase in blood pressure during the third trimester, and the presence of proteinuria and edema, in the absence of a history of hypertension were diagnosed as having preeclampsia. The third group represents women with chronic hypertension who experienced a significant increase in blood pressure with proteinuria, edema, or subjective symptoms that characterize preeclampsia.

In the chronic hypertensive group serial measurements from 16 weeks onward were obtained in 71% of the women and single measurements during the third trimester in the remaining 29%. In the other two groups this ratio is reversed, with 21% and 37% for serial measurements and 79% and 63%, respectively, for single measurements. For those with serial measurements, the third trimester average was used for the purpose of analysis.

Clinical management of chronic hypertension included antepartum nonstress tests, ultrasound examination, renal function studies, and fetal movement counting. Delivery before term was undertaken when there was fetal distress or significant maternal deterioration. Patients with preeclampsia were placed on magnesium sulfate on admission to the hospital. If the clinical picture improved in terms of blood pressure, urine output, lack of subjective complaints, and bio-

Table II. Outcome related to uterine systolic/diastolic ratios

	≤2.6 (n = 43)	>2.6 (n = 28)	p

chemical data (normal liver function, coagulation profile, etc.) they were weaned off the magnesium sulfate and transferred to the antepartum ward. The velocity data were not used for clinical management.

Statistical methods included calculations of means, standard deviations, standard error of a percentage, standard errors of difference between means, Student's *t* test, and the predictive values and efficiency of medical diagnoses.

Results

Table I displays a summary of some clinical and laboratory parameters for the women and newborn infants in this study. The group characterized as having chronic hypertension were those who demonstrated some elevation of blood pressure but few other problems. Their data do not differ significantly from a normal population, although there was a higher than average number of positive nonstress tests and cesarean sections. We used the chronic hypertensive group as statistical control subjects against both other groups. It can be seen that the clinical classification works very well in separating benign disease from more serious problems. The chronic hypertensive group with superimposed preeclampsia and those with preeclampsia alone differed in only a few parameters. One of these differences was in the number of cesarean sections, but this is probably a statistical aberration. The pure preeclamptic groups were younger and also all were nulliparous. The umbilical artery systolic/diastolic ratios were higher in both the preeclamptic groups but were only significant for the purely preeclamptic group. This may have occurred because the values for the chronic hypertensive groups were also at the lower limit of abnormal.

Table II divides the study group into normal and abnormal uterine artery systolic/diastolic ratios. Normal uterine artery values were obtained from the study of 60 normal pregnancies. In the last 14 weeks of pregnancy the uterine systolic/diastolic ratio is 2 ± 0.3. The velocity wave incisura, or notch, disappears by the twenty-sixth week of pregnancy. It can be seen that the uterine systolic/diastolic ratio clearly divided the patients into normal and abnormal groups. The two parameters that were not different were the average blood pressure and the percentage of low 1-minute Apgar scores. It should be noted also that most of the calculated differences were at a statistical level of <0.001, which indicates the strength of this new test.

The efficiency of a medical test and diagnosis is measured by the sensitivity and specificity as well as the predictive value of a positive or negative test. To carry out this calculation we selected the parameters of an optimum perinatal outcome, delivery at 37 weeks or beyond or a fetus weighing ≥2500 gm. These data are displayed in Table III.

It can be seen that calculations from the uterine velocity wave are more sensitive, specific, and predictive than the blood pressure, creatinine clearance, or uric acid levels. We did not have sufficient 24-hour protein

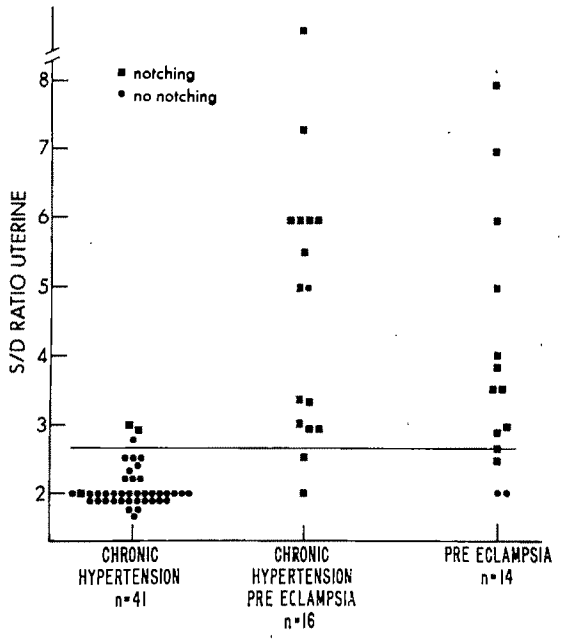

Fig. 2. Distribution of uterine systolic/diastolic *(S/D)* ratios within clinical classification of disorders caused by pregnancy hypertension.

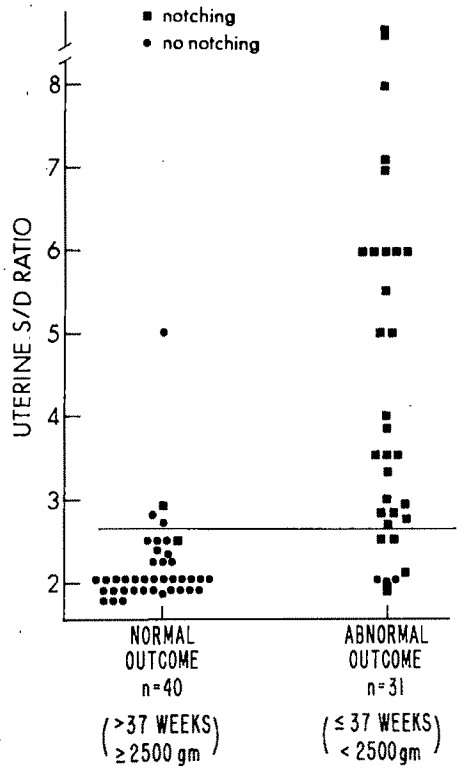

Fig. 3. Clinical outcome based on uterine systolic/diastolic ratios.

measurements to make similar estimates on this parameter. It is also interesting to note that a persistent notch in the uterine velocity wave is a more discriminating finding than measurement of the ratio alone. The presence of a notch is statistically significant against the other traditional measurements.

Fig. 2 provides distribution columns of ratios and notching within the designated clinical classifications. Again it can be seen that an elevated ratio or the presence of a notch provides virtual assurance of the presence of preeclampsia. Fig. 3 plots distribution columns for perinatal outcome as related to the uterine systolic/diastolic ratio and notching of the velocity waveform. With only a few exceptions a normal ratio was associated with a normal outcome. It can be noted that three of four women with normal ratios but having a persistent notch had abnormal outcomes, specifically, growth-retarded babies. In all three cases there were elevated umbilical artery systolic/diastolic ratios indicating significant placental disease. The one elevated ratio of 5 in the normal outcome group occurred as a single measurement late in the pregnancy. At that time the patient developed headaches, blurred vision, right upper quadrant pain, abnormal liver function tests, and was delivered of a 3985 gm baby. In all probability this was a gestational diabetic patient because the umbilical artery ratio was also elevated. In three other cases there were low birth–weight babies with normal uterine velocity waveforms. These women were delivered early because of the belief that the clinical situation was worsening. In one of these cases there was a probable error in diagnosis, since the woman continued to have hypertension and proteinuria months after the delivery. The other two cases had elevated umbilical artery systolic/diastolic ratios.

Fig. 4 displays the distribution of the perinatal outcomes of a normal and abnormal ratio and the percentage of low birth–weight babies and those who were growth retarded. It is clear that an abnormal ratio is associated with both premature delivery and intrauterine growth retardation.

Figs. 5 to 8 illustrate the patterns of development of uterine artery compliance in relation to the presence or absence of clinical disease. In normal pregnancy the uterine artery notching usually disappears by the twenty-sixth week and a normal ratio of 2 is seen from 28 weeks onward. As can be seen from these examples, several variations on the evolution of compliance can occur. Second-trimester measurements in the preeclamptic groups were not sufficient to know whether compliance was lost or never acquired.

Comment

Uterine and umbilical artery velocimetry provides information that is uniquely informative in the management of normal and abnormal pregnancies. In this paper, attention was directed to the role of these measurements in women suspected of being at risk for hypertensive complications of pregnancy. The abnormal

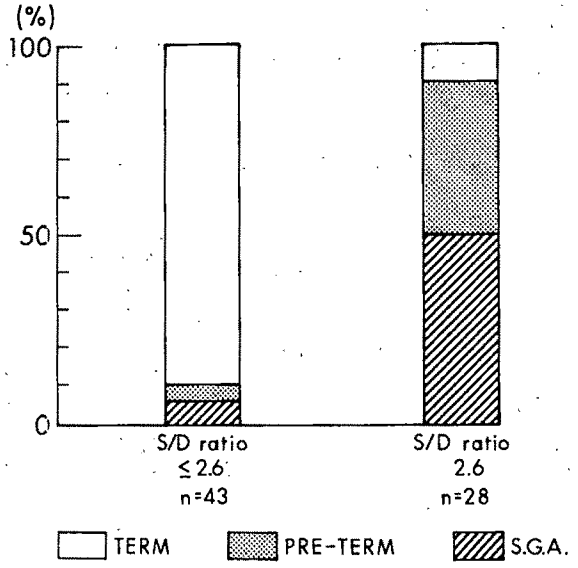

Fig. 4. Uterine vascular compliance and perinatal outcome. Data from Fig. 3 are displayed in this bar graph to show percentage of babies which were growth retarded and those who were average for gestational age but were delivered preterm.

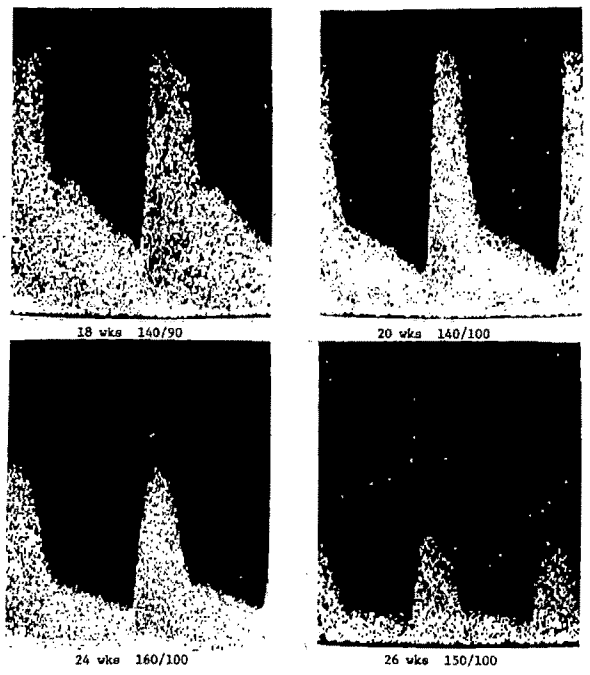

Fig. 5. Velocity waveform patterns of a woman with chronic hypertension who developed a normal vessel pattern by 24 weeks.

uterine artery velocity waveform has two easily measurable indices: the presence or absence of a notch in early diastole, and the peak-systolic/end-diastolic ratio.[11] If the ratio is elevated and a notch is present, the pregnancy suffers the consequences of inadequate nutrition and oxygenation.

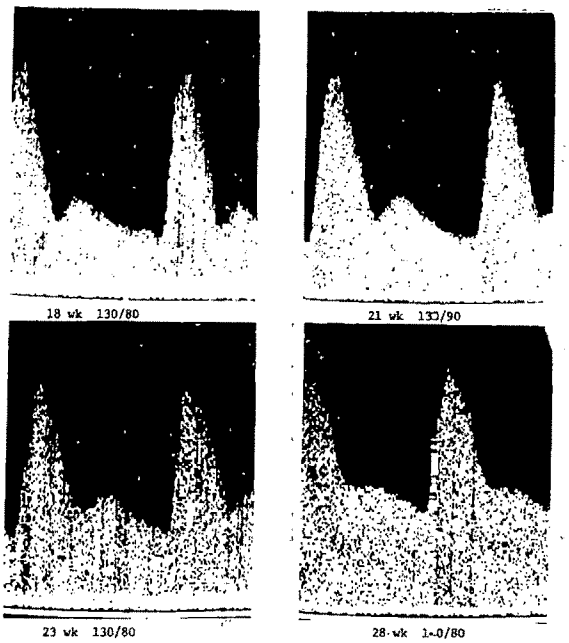

Fig. 6. Velocity waveform patterns of a woman with chronic hypertension in whom the normal vessel pattern did not develop until week 28.

To validate the usefulness of these measurements we analyzed their effect on perinatal outcome and the most common physical and chemical abnormalities seen in hypertension and pregnancy. The results revealed predictive values of ≥90% for both positive and negative tests. Thus for the first time the clinician has a tool that accurately describes the uteroplacental and fetoplacental circulation. Although velocimetry is only a component of flow, these studies demonstrate that for clinical circumstances it separates normal from abnormal. Of special interest is that the changes in uterine and umbilical velocimetry precedes by weeks or months the clinical manifestations of disease[13, 14] (Figs 6 to 8).

Campbell et al.[11] studied the uteroplacental circulation with use of a pulsed Doppler system coupled to a linear-array imaging of the branches of the uterine at the placental site. They created a calculation that was called the "frequency index profile." If a ratio calculation was applied to their derived waveform, the results were comparable to ours. When the normal waveform group was compared to the abnormal group, significant differences in outcome were recorded. These differences were not as large as those demonstrated in our study, probably because their patients were all seen at 35 weeks or later.[11]

Trudinger et al.[15] used the systolic/diastolic ratio for the analysis of uterine and umbilical velocity waveforms. They established a 95% value of approximately 1.8 for upper limits of normal with a mean of 1.5. They studied subplacental vessels only and the analysis was for the identification of infants who were small for ges-

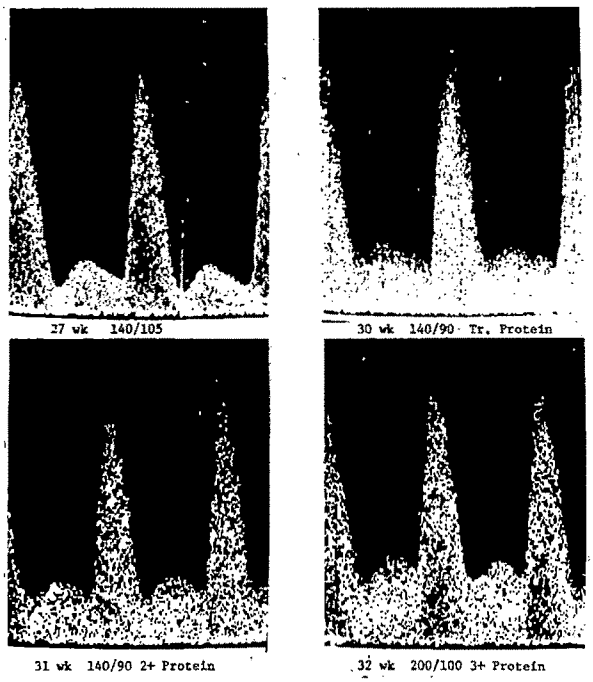

Fig. 7. Velocity waveform patterns of a woman with chronic hypertension who never did achieve a normal vessel pattern. She developed severe preeclampsia at 32 weeks.

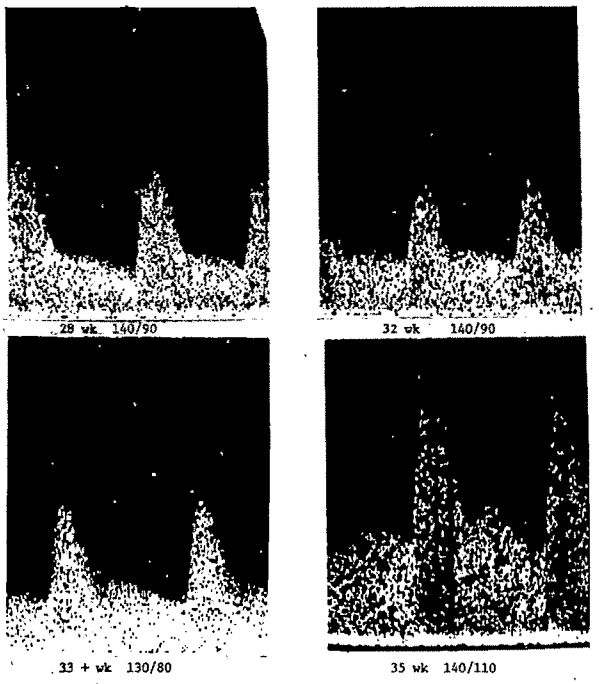

Fig. 8. Velocity waveform patterns of a woman with chronic hypertension who developed a normal vessel pattern and then reverted at 33 weeks. Preeclampsia was evident at 35 weeks.

tational age; therefore, their study is not comparable. As in our work, they also used a continuous-wave Doppler system, which is superior to a pulsed-wave system because of lower power density and lower expense.[15]

DeWolf et al.[16] have carried out systematic studies of the normal and abnormal vascular anatomy of the placental bed. In normal pregnancy trophoblastic erosion occurs in the spiral arteries during the process of placentation. In preeclamptic pregnancy "the myometrial segments of the placental bed spiral arteries are not invaded by cytotrophoblastic cells and do not undergo physiologic changes. They retain their musculoelastic arterial structure and, with the onset of the clinical signs and symptoms of preeclampsia, they are prone to develop hypertensive lesions."[16] The velocity waveform data complement these morphologic observations nicely in that the development of preeclampsia in most cases is associated with the failure of the development of normal low-resistance velocity flow in the uterine arteries.

The implications of the data recorded in this study are numerous. Hypertension is the most common medical complication of pregnancy. The blood pressure is a manifestation of a heterogenous group of disorders which may or may not impact on the pregnancy. Thus the ability to assess the functional state of the uterine and umbilical circulation provides the physician with an incisive probe that forecasts pregnancy outcome. This information provides a matrix on which treatment protocols can be devised. Although this represents another testing procedure during pregnancy, it should in the long run represent a net saving because the need for most nonstress tests and real-time ultrasound will be eliminated.

Discussion

Dr. Luis A. Cibils, Chicago, Illinois. This new approach in the series of papers coming from Dr. Schulman's department focuses on the blood supply to the intervillous space. In my discussion of his study of the umbilical arteries presented to this Society 2 years ago I elaborated on some crucial technical points and posed some questions that were never answered to my satisfactions.[1] I am glad to have been given the chance to review the application of the same technique and principles to the assessment of uterine arteries flow and thereby restate some of my points with the hope that this time I will be given the clarifications I requested.

The most basic questions were posed by Kurjak and Rajhvajn[2] in 1982 when they stated that "ultrasonic studies should be tested in conjunction with electromagnetic flowmeter measurements, but this can be done only in animal experiments." Up to the present time this has not been done, and neither the more refined technique of range-gated–pulsed method nor the much more crude method of "visual pattern recognition" used in the present study has been clearly proved to be accurate. In addition to the problem of accuracy of the analyzed data, one must consider the "cleanliness" of the signals obtained.

As Dr. Schulman stated, "a continuous-wave Doppler system provides an image of all vessels which are crossed." In this context it is practically impossible to obtain a clean signal through a probe with a diameter of 12 mm (not gated, not ranged) directed either at the vaginal fornices or the right and left lower quadrants of the anterior uterine wall. This is simply due to the anatomic complexity of the vessels involved. From early gestation on, it has been shown in humans that the arterial tree around the fornices is very prominent and branching.[3, 4] If one remembers that there is an extremely rich network of venous plexuses accompanying them, the idea emerges that a beam attempting to measure movement of red cells in a single vessel is almost impossible. The solution seems to have been the arbitrary definition of "a pattern" ascribed to some individual vessels. There is continuous flow in the veins and pulsatile flow in the arteries; how can they be separated when the maximum caliber of the uterine arteries has been measured to be 3.6 ± 0.9 mm[5] and the beam is 12 mm wide? And what is the more deeply situated vessels' contribution to the spectrum? How much does the venous flow raise the baseline of your spectrum, and how is this set? The vaginal route does not seem to be the solution to the problem Dr. Schulman encountered in 1984 (see Reference 15 of article) when he stated that "uterine artery measurement is much more complex . . . it is difficult to be sure which you are measuring (referring to uterine, hypogastric, or arcuate-radial waveforms). As the uterus grows larger, this becomes an even more difficult technical problem."

The abdominal transducer does not have a simpler vascular tree to traverse in human pregnancy. Dr. Elizabeth Ramsey made the most elegant studies and reconstructions to date of the intertwining of the arteriovenous tree throughout the primate gestation (rhesus monkeys and humans).[6, 7] Clearly one cannot separate the movements of red cells in the various vessels with use of the technique here discussed. The nonplacental areas of the uterus are only moderately less complex, as shown by arteriograms.[8] This is a blind method relying only on an arbitrary pattern that, taken by faith, would represent the flow through an artery. Again here one must restate the questions: How are the authors sure of what signals they are recording? What are the guidelines to set the cursor for reading the systolic and diastolic values? How are artifacts recognized? What is the effect on blood flow of localized uterine contractions occurring throughout gestation? In these areas a 12 mm beam encompasses more arterial branches than in the vaginal fornix, and they are of lesser caliber. Unless these basic questions are satisfactorily answered, there is no point in discussing the results offered to us.

DR. FRANK C. GREISS, JR., Winston-Salem, North Carolina. Basically I have all of the concerns that Dr. Cibils has. I have just one other comment. The sensitivity and specificity that Dr. Schulman showed indicate that whatever he is measuring is an apparent guide in terms of the development of pregnancy-induced hypertension.

DR. CHARLES BRINKMAN, Los Angeles, California. I had an opportunity when I was in Britain to see some of this work, and I certainly can agree with Dr. Schulman that the pattern recognition is possible. Even with an imaging technique and coupled pulse Doppler, one can pick out the various vessels just by the patterns.

The concern I have is the location from which you taken these various recordings. As we all know, the placenta of a hypertensive patient has varying degrees of infarction. If you look at it histologically, some of the vessels are markedly involved while others are much less involved. I wonder what the reproducibility of this technique is when you do not know from which vessel you are recording.

My question is: What is the reproducibility of this method in the same patient? I have great concern that each measurement may be from a different vessel, so I think reproducibility is an important question with this particular technique.

This is a very exciting study, and I think that as the technology catches up, it may become clinically useful.

DR. SCHULMAN (closing). It is not unique in science to raise theoretical objections to experiments, but the proof of the study is the experimental data and its reproducibility, so despite the objections, we, having done more than a thousand of these determinations, have little doubt about what we are seeing and about what we are measuring.

Two other laboratories, Dr. Campbell's and that of Dr. Trudinger in Australia, have obtained similar measurements; although their studies were carried out primarily in the last 5 weeks of pregnancy, the data are essentially identical.

Obviously, we took it one step further in describing an evolutionary process and the clinical outcomes.

In terms of the basic experiments, we certainly look forward to those being done. One chooses an experimental approach. One also chooses the subject to work on, animal versus human. The foundation for this work would not be answered by use of a flowmeter, since velocity is derived by dividing flow by the area distal to the point of measurement, for example, the resistance. Velocity is an understandable concept and will stand on its own as an important physiologic observation.

It has been our belief that the human data which are spilling out from half a dozen other laboratories around the world and particularly in the umbilical velocity work, are so consistent and so reproducible that I do not think it is necessary for us to undertake animal studies, but we certainly look forward to other people doing it. We think there is important human information that can be obtained immediately.

How does one obtain a clear signal? There are two ways to differentiate a vein from an artery. One can select a bidirectional system with a split screen, and it clearly shows flow going in two different directions. Second, the venous signal looks nothing like an arterial signal. It is a smooth, oscillating waveform. It does not have pulsations.

We record all our examinations on tape, so it is easy to review over and over again. It is a simple technical matter to move the probe to slightly different angles to obtain the maximum signal and the signal that you desire. It is easy to eliminate the venous signals in most circumstances. As one becomes experienced, one can recognize the overlying venous signal, and if it is interfering with the diastolic trough, one is obviously not going to use that particular signal in terms of describing the data.

I do not think this is a matter of faith. I have seen enough apples and oranges to be reasonably convinced that I know what they are when I see them.

We have with the probe directly on the vessel done this intra-abdominally in enough circumstances to be convinced that we are reasonably accurate about what we are seeing.

Regarding Dr. Greiss' comment, I did not mean to imply that I had determined the etiology of preeclampsia. I have simply demonstrated another associated physiologic event that occurs months to weeks before the clinical picture presents itself.

In answer to Dr. Brinkman's comments, it is possible to do many things with these probes. For example, in the early second trimester of pregnancy, you will see differences in the arcuate vessels and get different ratios. If you have the woman tilted slightly, you can move the probe slightly laterally and in many circumstances can follow the uterine artery right out to the iliac vessel.

The proximal uterine represents the summary of what is going on in all the arcuates that are involved, but once you get past a certain gestational age, a period we have identified as being about 26 weeks, they all measure out the same.

The intraobserver error is about 6%. When it is done day after day after day by the various people who work with us, we obtain the same results. Two nurses do most of our measurements at the present time.

Risk factors for the development of diethylstilbestrol-associated clear cell adenocarcinoma: A case-control study

Arthur L. Herbst, M.D., Sharon Anderson, Ph.D., Marian M. Hubby, Ph.D., William M. Haenszel, Dr.P.H., Raymond H. Kaufman, M.D., and Kenneth L. Noller, M.D.

Chicago, Illinois, Houston, Texas, and Rochester, Minnesota

Factors related to the risk of developing clear cell adenocarcinoma in diethylstilbestrol-exposed women were investigated in 156 patients in the United States with clear cell adenocarcinoma and documented diethylstilbestrol exposure (Registry cases) and 1848 diethylstilbestrol-exposed women of similar age without cancer (National Cooperative Diethylstilbestrol Adenosis Project). Diethylstilbestrol dosage patterns, the use of other hormones, mother's age and pregnancy history, and daughter's birth month, birth weight, and age at menarche were compared. The relative risk was higher for those whose mothers began diethylstilbestrol before the twelfth week of pregnancy and for those who were born in the fall (winter conception). Maternal history of at least one prior spontaneous abortion elevated the risk. Supportive evidence for the difference in birth month distribution was also found by a comparison with United States vital statistics. Each factor was confirmed to be significant in a multivariate logistic model that examined all of them with region and year of birth adjusted. (Am J Obstet Gynecol 1986;154:814-22.)

Key words: Intrauterine diethylstilbestrol exposure, risk factors for clear cell adenocarcinoma

The association between intrauterine exposure to diethylstilbestrol and the subsequent development of clear cell adenocarcinoma of the vagina and cervix was established in 1971.[1-3] Subsequently a registry was founded for the study of these tumors in women born after 1940, irrespective of the maternal medication history. Information concerning the epidemiologic, clinical, and pathologic aspects has been covered in a number of reports[4-7] and currently more than 500 cases are accessioned. Diethylstilbestrol-associated cases make up approximately two thirds of the accessioned cases, most of which originated in the United States; additional cases have been reported from Canada, Mexico, Western Europe, Australia, and Africa. Previous findings indicated that the youngest diethylstilbestrol-exposed patient to develop clear cell adenocarcinoma was 7 years of age at the time of diagnosis, and a marked rise in the age incidence curve occurred at age 14 years. Evaluation of the incidence of diethylstilbestrol-associated cases in women born in the peak years of diethylstilbestrol use indicated that the increase in the occurrence of clear cell adenocarcinomas paralleled the changes in annual sales of 25 mg tablets by one large diethylstilbestrol drug manufacturer.[4]

In a preliminary study of diethylstilbestrol-exposed clear cell adenocarcinoma cases and control subjects the pattern of maternal diethylstilbestrol ingestion suggested that the risk of development of clear cell adenocarcinoma was higher among those whose mothers began diethylstilbestrol earlier in pregnancy.[6] This report was based on univariate frequency distributions and it was not possible at that time to control for other maternal, host, or exposure variables or to test for interactions among them.

The current study was undertaken to try to delineate the specific features of diethylstilbestrol exposure that may predispose to the occurrence of clear cell adenocarcinoma and to ascertain if there are identifiable maternal or host characteristics that affect the risk of appearance of this cancer. To evaluate these questions a case-control study has been undertaken in which data on diethylstilbestrol-exposed individuals with and without clear cell adenocarcinoma were available for analysis. The data allow multivariate analysis of potential risk factors and their interactions.

Methods

Initial classification of cases. For cases of clear cell adenocarcinoma, duplicate copies of hospital records and physician notes were obtained, including the obstetric records when available. Slides of the tumor and

operative specimens were reviewed by Dr. Robert E. Scully or colleagues* in the Department of Pathology, Massachusetts General Hospital, Boston.

For diethylstilbestrol-associated cases details of the maternal history are recorded, including the level of precision regarding the time in pregnancy when diethylstilbestrol was begun and the duration and dose of therapy. For example, if the date of the last menstrual period and the exact date of starting diethylstilbestrol were known, the information regarding the time of initiation of diethylstilbestrol during pregnancy (in days from the last menstrual period) would be recorded as accurate to 1 day. Alternatively, if it was known that the drug was started in a certain week of the pregnancy and the exact date of the last menstrual period was available, then the information would be classified as being accurate to within 1 week. For time of starting diethylstilbestrol during pregnancy the data were classified as being accurate to within 1 day, 1 week, 2 weeks, 1 month, 2 months, or one trimester. Similar refinements were used for duration of therapy, and dosages were recorded as accurate to 1.0, 10, 100, 1000, or >1000 mg.

In all of the cases in the current study, written information from the prenatal, hospital, or pharmacy records was available. In the analysis of diethylstilbestrol exposure patterns the level of precision for day diethylstilbestrol was begun was ≤2 weeks, for duration of diethylstilbestrol use the precision also was ≤2 weeks, and for total dose given the precision was ≤100 mg.

The control subjects consisted of diethylstilbestrol-exposed women without cancer who were identified through physicians' records by the National Cooperative Diethylstilbestrol Adenosis (DESAD) Project.[8, 9] The national DESAD project began in 1974 to identify women exposed in utero to diethylstilbestrol and has provided annual examinations and questionnaires in order to investigate the long-term effects of diethylstilbestrol exposure. Five centers have participated in the project (Baylor College of Medicine, Houston; Cedars-Sinai Medical Center, Los Angeles; Gundersen Clinic, LaCrosse, Wisconsin; Massachusetts General Hospital, Boston; Mayo Clinic, Rochester, Minnesota).† Prenatal records were reviewed to identify individuals who were then traced and recruited for follow-up (record review participants). Entries in the prenatal record regarding diethylstilbestrol medication (last menstrual period, date of initiation, dose, dates of change in dose, and dates of ending medication) were recorded. Other DESAD project participants were referred by physicians or were self-referred, but only those identified by record review were included in the present case-control comparison.

Table I. Variables compared in cases and controls

Daughters
Birth year, birth month
Region, state of birth
Race
Birth weight
Age at menarche
Diethylstilbestrol exposure in utero
Day diethylstilbestrol began
Duration of diethylstilbestrol exposure
Total dosage of exposure
Progesterone in addition to diethylstilbestrol
Mothers
Age
Prior No. of pregnancies
Prior spontaneous abortions
Prior stillbirths
Prior infant deaths

The record review daughters from the DESAD project provide the least biased data in terms of the accuracy of the information on exposure to diethylstilbestrol and are the most representative data available on diethylstilbestrol-exposed mothers and daughters in the United States.

The criteria for recording diethylstilbestrol dosage and other study variables were reviewed at the beginning of this investigation by DESAD and Registry staff to determine which variables were recorded in a similar fashion by the two groups and thus could be accurately transformed into identical variables for precise comparisons (Table I).

Maternal reproductive history for both cases and controls was ascertained from the prenatal records and from questionnaires filled out by the mothers. Numbers of prior pregnancies, prior spontaneous abortions (loss before the twentieth week), and prior perinatal loss (stillbirths and infant deaths) were recorded. Also recorded were the mother's age, daughter's birth weight, and medications other than diethylstilbestrol prescribed in the pregnancy. Although data on complications in the index pregnancy such as prior infertility, bleeding, cramping, diabetes, or hypertension were included in both groups, the information was recorded with the use of different criteria and an accurate comparison of these variables could not be performed in the current investigation.

The daughter's age at menarche, marital status, oral contraceptive use, and pregnancies were recorded at the time of follow-up examinations and by question-

*Grouping of states as divided into regions defined by the United States Bureau of the Census.

naires. The information on oral contraceptive use was recorded somewhat differently in the two studies, and the relatively small number of registry cases with comparable lifetime experience of oral contraceptive use and pregnancies before the diagnosis of cancer did not allow meaningful comparison.

Estimates of risk factors. Both the cases and controls in this study were limited to daughters born in the United States with written documentation of diethylstilbestrol exposure. The birth years of the cases and controls differed significantly (Table II). Because of the changes in diethylstilbestrol prescribing patterns during the years between 1941 and 1971, only those control subjects who were born during the same period as the cases (1945 to 1965) were included in the analyses, and all the multivariate analyses were adjusted for birth year.

The distribution by region of birth of the cases and controls also differed significantly, mainly because of the fact that the control subjects came from only five examining centers while the cancer cases have been reported from all areas throughout the United States. In order to take this into account, all multivariate analyses were adjusted for region of birth, as defined by the United States Bureau of the Census. Separate analyses within each region were done and the results were similar to those reported in this paper for all of the variables.

Initial univariate comparisons of the frequency distributions for the cancer cases and DESAD controls were done with the use of χ^2 tests (two-sided 0.05 level). Continuous variables were also compared with independent t tests. Multiple logistic discriminant analyses, adjusted for region and year of birth, were then used to identify significant variables.[10] All of the logistic analyses were done at the 0.05 level of significance. Stepwise procedures were used to identify the most significant variable from the set being analyzed. The analyses were done in two stages, looking first at diethylstilbestrol exposure variables. Then the maternal and host variables were examined with correction for the effects of the diethylstilbestrol exposure variable that was found to be significant, for instance, "day DES began" (see Results). This procedure allowed separate evaluation of the additional effects of maternal and host variables on diethylstilbestrol-associated cancer risk.

Stage 1: Evaluation of diethylstilbestrol effects. The effect of the day the mother began diethylstilbestrol and the duration and the total dose of diethylstilbestrol exposure were analyzed, with the region and year of birth controlled. The exposure variable that we found to be significant was the day diethylstilbestrol was begun in pregnancy. This variable was later categorized into four groups (before seventh week, seventh to eighth week, ninth to twelfth week, and ≥13 weeks) in order to present more clearly the risks associated with starting diethylstilbestrol in each interval during pregnancy (Table III). The effects of the duration and total dose of diethylstilbestrol were not significant, perhaps because of the small number of cases with precise and complete information on these variables. Thus the duration of diethylstilbestrol therapy during pregnancy and the total dosage ingested by the mother were both deleted from the analyses. The adjusted relative risks (odds ratio) presented in Tables III, IV and V were calculated from the logistic model and refer to the risk in one category versus a risk of 1.00 assigned to the last category. For example, in Table III the risk associated with the mother's beginning diethylstilbestrol before the seventh week was compared to the risk for those whose mothers began diethylstilbestrol at 13 weeks or later.

Stage 2: Evaluation of other maternal and host characteristics. In the second stage, stepwise logistic discriminant analyses were then done for other maternal and host characteristics in order to determine which variables significantly increased or decreased the risk, with the effect of day of beginning diethylstilbestrol exposure taken into account. Three control variables—region of birth, year of birth, and day diethylstilbestrol began—were all retained in the model for the analysis of the other characteristics. Initially any variable that was continuous was so treated, then later categorized into two to four groups in order to display the results

Table III. Relative risk for time of starting diethylstilbestrol in pregnancy

Diethylstilbestrol began	*Cases*	*Controls*	*Unadjusted relative risk*	*Adjusted relative risk**	*95% Confidence interval*
Before week 7	21	188	4.52	3.65	1.84-7.25
Week 7-8	35	260	5.45	4.84	2.63-8.90
Week 9-12	41	449	3.76	3.48	1.94-6.25
Week 13 or later	17	688	1.00	1.00	
Total	114	1585			

The risk in each time interval is compared to a risk of 1.00 for the last time interval.
*Adjusted for region and year of birth.

in Table IV in a more simplified manner. The adjusted relative risks shown are calculated from the logistic model.

Finally, a stepwise logistic discriminant analysis was done, with incorporation of the significant variables from the maternal and host discriminant analyses, to estimate the effect of each on the relative risk of developing clear cell adenocarcinoma (Table V). The cases included in this final model had accurate information for all of these variables.

Supplemental analyses with cross-tabulation by the Mantel-Haenszel method yielded estimates of odds ratios consistent with those reported in Tables III, IV, and V.

For the comparison of the birth months of the case subjects to birth months expected in the general population, United States Census data were examined for each year, for the race and state of birth of each case subject. For example, for a cancer patient who was white, born in 1951, in California, the 12 probabilities of a white individual being born in January, February, March, etc., in California, in 1951, were calculated from the census figures. The expected probabilities of birth in January, February, March, etc., were added up for all the cases to calculate the mean expected probabilities shown in Table VI and Fig. 1.

Results

Diethylstilbestrol exposure patterns. Written documentation of diethylstilbestrol exposure was available on 156 patients born in the United States with clear cell adenocarcinoma and 1848 control subjects born in the United States without cancer (born 1945 to 1965), from the "Record Review" category of the DESAD project. Table II displays the demographic characteristics of each group. The significant differences between these groups with respect to year ($p = 0.0001$) and region of birth ($p = 0.0004$) were taken into account by systematically adjusting for these two variables in the results presented.

Evaluation of the maternal records for the cancer cases indicated that the most precise and complete information regarding diethylstilbestrol exposure was the day medication was started during pregnancy. The duration of treatment and the total dosage of diethylstilbestrol ingested were evaluated and their effects were not significant, perhaps because of the small number of cases with precise and complete information. Stepwise logistic discriminant analysis found the day diethylstilbestrol was started to be significant ($p < 0.05$). The results presented are limited to those cases for which the timing of diethylstilbestrol treatment during pregnancy could be ascertained within 2 weeks of the last menstrual period. The comparative distribution of these cases and controls is shown in Table III. The relative risk, adjusted for differences in birth year and region, is also shown with 95% confidence intervals.

In all of the cancer cases except one, the mother began diethylstilbestrol before the nineteenth week of pregnancy. In that case the record indicates diethylstilbestrol was begun in the thirty-second week of pregnancy (150 mg given for an unknown length of time). The relative risk of cancer development is lowest for those daughters whose mothers began diethylstilbestrol after the twelfth week of pregnancy. The apparently smaller relative risk during weeks 0 to 7 was investigated further by examining the histories of the 21 cases in which diethylstilbestrol was begun before the seventh week of pregnancy. Only two of the mothers began diethylstilbestrol in small doses before conception for infertility therapy and continued taking it, while the other 19 began diethylstilbestrol as pregnancy therapy during the fifth or sixth week. Supplemental analysis with cross tabulation by the Mantel-Haenszel method indicated some regional variation in the risk level for each of the time intervals; however, it confirms that the risk is lower for those whose mothers began diethylstilbestrol late in pregnancy.

Additional risk factors—Maternal and host characteristics. In addition to investigating the role of diethylstilbestrol exposure, a second goal of this study was to determine if any maternal or host characteristics either significantly decreased or increased the risk of developing clear cell adenocarcinoma. Thus all analyses

*Adjusted for region and year of birth and early or late exposure to diethylstilbestrol (day began ≤63 or >63).

investigating maternal and host characteristics are adjusted not only for region and year of birth but also for time diethylstilbestrol was begun.

Table IV presents the relative risk estimates for the maternal and host characteristics. Most of the comparisons did not yield significant differences. Progesterone and steroidal estrogen were given in addition to diethylstilbestrol in comparable proportions of cases and controls. Distributions of mother's age and age of menarche were the same in both groups. There are statistically significant adjusted relative risks for the fall season of birth (reflecting winter season of conception) and for maternal history of at least one spontaneous abortion.

When the data were evaluated for daughters with premature birth (infant's birth weight <2500 gm), it was found that this group had an increased risk of developing clear cell adenocarcinoma, with region and year of birth and time of exposure to diethylstilbestrol adjusted (relative risk = 2.37); however, birth weight information was available for only 84 of the cancer cases and only one third of the cases (54) had information on the four variables (time of diethylstilbestrol exposure, season of birth, history of spontaneous abortion, and premature birth). The small numbers of cases with complete information on all of the variables prevented meaningful inclusion of premature birth as a factor in the subsequent multivariate logistic model.

To determine the relative importance of the factors identified in Table IV on the risk of developing clear

*Adjusted for birth year and region. All factors had to be known for the case to be included in the logistic model.

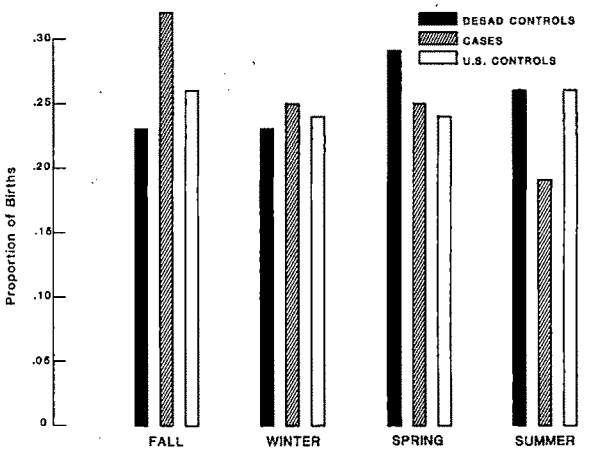

Fig. 1. Season of birth for controls, cases, and United States population for the states, years, and race of cases.

cell adenocarcinoma, a final discriminant analysis was performed, which included the day diethylstilbestrol was begun (day 63 or earlier or later than day 63), season of birth (fall or other), and prior spontaneous abortion. The adjusted relative risks and their confidence intervals are presented in Table V. There was no statistically significant interaction among the three variables considered (time of beginning diethylstilbestrol, season of birth, and prior spontaneous abortion).

The distribution of birth months for the cases was also examined in comparison to the expected distribution calculated for each case with the use of United States National Office of Vital Statistics data for the year of birth, state, sex, and race of each case to ascertain if the differences noted between the cases and controls also existed when the distribution of cancer cases was compared to that in the general United States population. The difference from the expected distribution is shown in Table VI ($\chi^2 = 19.53$, 11 df, $p = 0.052$). This result is supportive of a difference in birth month distribution in the cancer cases in the months of September through December, corresponding to conception in the "flu" months of December through March. Fig. 1 displays the distribution of season of birth for cases and controls and for United States women born in the same states and years as the cases. The controls are seen to be representative of the United States natality experience as reported by the National Office of Vital Statistics.

Comment

These results of a comparison between diethylstilbestrol-exposed women with and without clear cell adenocarcinoma indicate several of the factors that are associated with the risk of developing this cancer. The Registry for Research on Hormonal Transplacental Carcinogenesis has collected data on most of the cases of clear cell adenocarcinoma of the vagina and cervix that have occurred in the United States in women born since 1940. This collection of cases is the sole source of centralized data available for the investigation of these tumors. The DESAD project, from which the controls were drawn, has participating centers in four areas of the country, mainly associated with large teaching hospitals. The DESAD centers differed from each other on the variables of DES exposure, birth weight, mother's age, and mother's number of prior pregnancies and spontaneous abortions so that regional variation must be taken into account. The centers may not represent the entire country, but the pooled data give a good approximation and provide the most representative comparison data available. Analyses done within each

region of the country are consistent with the results presented, and the inferences did not differ with or without adjustment of the region of birth.

The results of the analyses on diethylstilbestrol exposure patterns, adjusted for differences between the clear cell adenocarcinoma cases and DESAD controls in region and year of birth, indicate a lower risk for cancer among those women whose mothers began diethylstilbestrol after the twelfth week of pregnancy. This association had been indicated in a prior comparison of the distribution of the week diethylstilbestrol was begun between diethylstilbestrol-exposed clear cell adenocarcinoma cases and controls.[6] In many of the prenatal records reviewed there was sparse and imprecise information available on the duration and the total dosage of DES expsoure in pregnancy and the limited nature of the data prevented conclusions being drawn about the role of these exposure variables in the risk of clear cell adenocarcinoma. Diethylstilbestrol prescribing patterns varied in different parts of the country and in different years and the exposures differed among the DESAD centers and between the regions described in these results.[8] There was regional variation in the amount of risk elevation associated with early time intervals of beginning diethylstilbestrol but the regional analyses confirm the lower risk for those whose mothers began diethylstilbestrol later than the twelfth week of pregnancy, as presented in the pooled national data (Table III). The risk does not appear to decline progressively concomitant with diethylstilbestrol exposure beginning later in pregnancy; that is, the risk is greater for those whose mothers began diethylstilbestrol in weeks 7 and 8 than for those whose mothers began diethylstilbestrol before week 7. It is not possible from the available data to explain this seemingly paradoxical result. For example it is conceivable that diethylstilbestrol dosage may also be a significant risk factor that was not detected in the current analyses because of the lack of sufficient cases with precise data. If this were true and a high proportion of the mothers who started diethylstilbestrol before week 7 also received smaller dosages of diethylstilbestrol then the observed result of a smaller risk before the seventh week would be obtained. Numerous other speculative explanations exist.

It is not possible to determine from these data if the elevated risk for clear cell adenocarcinoma development among those whose mothers began diethylstilbestrol before the twelfth week in pregnancy is directly related to early diethylstilbestrol exposure or mediated by the development of vaginal adenosis and associated epithelial changes that occur more frequently in women exposed early to diethylstilbestrol and also to higher doses.[9] Areas of vaginal adenosis with the most extreme atypia and a tuboendometrial glandular pattern are frequently topographically associated with tumor areas.[11]

Among the other maternal and host characteristics investigated, the mother's history of prior spontaneous abortion, daughter's low birth weight, and fall season of birth were found to be significant risk factors in addition to early diethylstilbestrol exposure.

The elevated rate of prior spontaneous abortion among the mothers whose daughters developed clear cell adenocarcinoma raises the possibility that an inherited genetic predisposing factor may have played a role in some of these cases. In the original case-control studies in 1971, comparing women with clear cell adenocarcinoma and controls, higher rates of complications such as bleeding and prior spontaneous abortion had been noted in the maternal histories of the cancer cases, as was a higher incidence of ingestion of diethylstilbestrol, which was frequently prescribed for these pregnancy complications.[1,2] It has been suggested that the maternal history of spontaneous abortion itself could result in an individual that is more susceptible to clear cell adenocarcinoma and this susceptibility may have been a more important factor in cancer development that the association with exposure to diethylstilbestrol.[12] The current case-control results do not support this explanation. Although the maternal spontaneous abortion history is a risk factor, the time of exposure to diethylstilbestrol during the pregnancy remains significant even after the maternal history of prior spontaneous abortion is adjusted (Table V).

The higher frequency of birth weight <5.5 pounds in the cancer cases compared to the DESAD controls may also suggest maternal complications as predisposing factors in cancer development or an inherent disadvantage in premature babies in resisting subsequent carcinogenic factors such as viral infection. Such interpretations must be tempered however, since data on birth weight were available in only 84 of the 156 cases studied.

The analyses of month of birth show a prevalence of fall births in the cancer cases whether compared with births of the DESAD controls or to the birth month distribution expected from United States census figures. Patients born in the fall will have been conceived primarily in the winter months during the prevalence of influenza virus. The regional distribution of cases and controls between cooler winter areas (north central and northeast) and warmer areas (south and west coasts) was similar. Viruses have been associated with some cancers and animal studies have suggested immunologic deficiency after diethylstilbestrol exposure in rodents.[13] Thus a viral role in clear cell adenocarcinoma is suggested but these data do not permit more than speculation in regard to a potential role. It is also conceivable that the observed differences are artifactual

and not indicative of any influence on the development of clear cell adenocarcinoma.

It appears that the time of exposure to diethylstilbestrol during pregnancy is a critical factor in the risk for clear cell adenocarcinoma and that, after its effect is adjusted, premature birth, fall birth season, and a maternal history of spontaneous abortions also appear to be implicated.

We are grateful to all of the investigators of the DESAD project for their help in making these data available, and to Diane Anderson of the Registry at the University of Chicago for valuable assistance.

Discussion

DR. HUGH M. SHINGLETON, Birmingham, Alabama. I congratulate Dr. Herbst and his associates for their continuing effort to identify the specific risk factors for clear cell adenocarcinoma in diethylstilbestrol-exposed women.

Some of my remarks were provided by Seng-Jaw Soong, Ph.D., biostatistician for the Comprehensive Cancer Center at the University of Alabama at Birmingham. We compliment the authors for the excellent statistical analysis using univariate and multivariate analytical procedures, in particular the logistic regression model.

In considering the manuscript, one immediately runs into problems of numbers. Missing data have undoubtedly limited flexibility and usefulness of the multivariate analysis and the interpretation of results. Starting with 500 cases of adenocarcinoma accessioned into the registry, one must first delete the one third whose cancers are not diethylstilbestrol associated. In further limiting the analysis to those with the most data on 15 variables (ten daughter and five maternal related) one comes down finally to 156 individuals or less. Indeed, the totals considered in the various tables range from 84 to 156, nine different totals being portrayed. The most important factor, time of exposure to diethylstilbestrol, was determined on analysis of data from only 114 cases. Record-review daughter controls from the DESAD project were selected because of the availability of the "least biased and most representative" data available on diethylstilbestrol-exposed mothers and daughters in the United States. However, since only a subset of these data are used in this multivariate analysis, are the subsets unbiased and representative?

In regard to Table V, we were unable to determine the number of cases and controls that were used for this final analysis. Concerning the relative risks shown for early and late exposure to diethylstilbestrol, we felt that the groupings above and below 63 days were somewhat arbitrary and difficult to reconcile with the groupings in Table III, which divided the exposure in the categories before the seventh week of pregnancy, the seventh to the eighth week, the ninth to the twelfth week, and 13 weeks and beyond. In regard to the season of birth, where the fall season was compared with the remaining seasons, we also could not determine the reason for selecting the fall for comparison when on Table VI February, March, and April seemed equally attractive. Since fall deliveries imply a winter conception, was consideration given to the possible influence of other drugs taken during the winter season, especially over-the-counter drugs? Furthermore, was patient compliance in taking the diethylstilbestrol itself considered?

In summary, even with the limitations, this undoubtedly is the best information available, or likely to be available, on the subject. I would like to ask Dr. Herbst two questions: (1) How many cases and controls were included in the final analysis (Table V)? (2) Considering the very low relative risk of women who received steroidal estrogens along with the diethylstilbestrol, might the estrogens actually be a protective factor?

Were the subsets unbiased after we got through looking at those we had the information on? Obviously,

there is no way we can answer that. We have to assume that there is no reason for this type of precision to introduce bias into the analysis, but that is speculation.

Could drugs other than those we talked about with the viruses and the season of birth be involved in the genesis of this entity? The answer is, of course, they may be, but we do not have any information so we can just guess.

Dr. Shingleton wondered why 63 days was chosen in the final model. The reason for that is half the patients' mothers started diethylstilbestrol before the sixty-third day and half after the sixty-third day. Any other cutoff point could have been picked. The results would have been exactly the same, but that is why that point was chosen.

For our definition, the fall season of birth means September, October, and November, so we did not choose the 3 months that Dr. Shingleton mentioned. Again that is arbitrary, but that is the way we did it.

I do not believe steroidal estrogens have a protective effect. They were used proportionally about the same in both the cancer cases and in the noncancer cases. Although the relative risk was less than 1, the 95% confidence limits overlapped 1, and I do not believe that that is a biologically important fact.

As far as Table V was concerned, there were 104 cases in that particular analysis and 1323 controls.

As far as the other questions, Dr. Jones asked us about family history. We have looked into that in some of our other studies. We did not look into it in this study because those data were not recorded, and all we can say so far, particularly in the first study that we did in 1971, is that it was not an important factor.

Dr. Howard Jones III, Nashville, Tennessee. In this paper the authors have evaluated the relationship between cancer and the effects of diethylstilbestrol in both the mothers and the daughters and associated the fertility problems but have not considered in their analysis other factors that we know to be related to cancer, such as a family history of cancer, smoking, and so forth. I wonder if they had considered including these factors in their analysis of cancer risk in these patients?

Dr. Charles E. Flowers, Birmingham, Alabama. Many of these patients were from Boston, where Dr. Priscilla White was administering hormone supplements to her diabetic patients. Could this have been of any significance?

Dr. E. Stewart Taylor, Denver, Colorado. I was interested in the analysis that had to do with the increased number of spontaneous abortions that occurred in patients whose offspring had an increased incidence of adenocarcinoma of the vagina.

I wonder if that is not because patients with a previous history of many abortions came early and had enthusiastic treatment with large doses of diethylstilbestrol compared with those who just casually received the drug for other reasons.

Dr. Richard K. Miller, Rochester, New York. With diethylstilbestrol exposure, the medical community has been primarily concentrating on prenatal factors that may modify the incidence of vaginal tumors. Is there any possibility that postnatal factors and complications may also be important? In particular, have you, Dr. Herbst, investigated the relationship between prenatal diethylstilbestrol exposure and postnatal use of oral contraceptives?

Dr. Herbst (Closing). First, regarding the issue of the number of cases, Dr. Shingleton is absolutely correct. We were limited by the numbers that were available. In other words, we did not do the analysis unless there was written documentation of the diethylstilbestrol exposure, so that resulted in the 156 cases. Then, in some of the cases, all of the information was just not available.

We did require a high precision for the data to be analyzed. For example, for the analysis on the time in pregnancy the diethylstilbestrol was started, we either knew the precise day it started or we knew that information to be within 2 weeks of the last menstrual period. If there was written verification that the mother took the diethylstilbestrol but we did not know within 2 weeks of the last menstrual period when she started it, she could be in some of the analyses but not the time started analysis.

I would say the same thing about oral contraceptives. I cannot say they are not important. We have no information that they are important. We have looked at that, and I think it may be worthwhile to point out that among many of these cases, the young women were virginal at the time they developed cancer. Not only was there no oral contraceptive exposure, there had not been any sexual exposure, so although oral contraceptives might have some role, there is no suggestion that they do at all.

As far as Priscilla White's diabetic series is concerned, they have been examined in Boston. They do have vaginal adenosis and other diethylstilbestrol-associated changes. I am not aware of any cases of cancer in that group. However, if my memory is correct, there were about 700 daughters in that series and the risk of the cancer developing is of the order of ≤ 1 in 1000; therefore, it is not surprising to have a series of 700 individuals and have no cases of cancer. However, they definitely have the diethylstilbestrol-associated changes.

As far as spontaneous abortions are concerned and Dr. Taylor's statement about the mothers receiving diethylstilbestrol earlier in pregnancy, I think that is clearly a possibility. In this particular analysis, the history of spontaneous abortion was present in both the controls and the cancer cases, and for some reason spontaneous abortion was more frequent in the cancer cases. For that reason it turned out to be statistically important, so maybe the old idea that was brought up many years ago, of the bad egg, may be a possibility, but again it is just speculation.

Effect of induced oligohydramnios on fetal lung development

Jeffrey C. King, M.D., Wayne Mitzner, Ph.D., Arthur B. Butterfield, D.V.M., Ph.D., and John T. Queenan, M.D.

Washington, D.C., and Baltimore, Maryland

To investigate the impact of oligohydramnios on fetal growth, development, and lung function, amniotic fluid was shunted from alternate gestational sacs into the maternal peritoneal cavity at 23 days' gestation in the fetal rabbit. Uninstrumented fetuses served as controls. Oligohydramnios was confirmed at the time of planned cesarean delivery on either day 26 or 28. Fetuses subjected to prolonged oligohydramnios had significantly decreased body weight at 26 ($p = 0.002$) and 28 days ($p = 0.007$). Similarly, lung weight was decreased at 26 ($p = 0.02$) and 28 days ($p = 0.005$). There was a trend toward decreased maximum lung volume for instrumented fetuses at 28 days ($p = 0.07$). Deflation limbs of the pressure-volume curves revealed significantly increased air trapping for instrumented fetuses at 28 days. These studies suggest not only a detrimental effect of oligohydramnios on fetal body and lung weight but also a beneficial effect of premature rupture of membranes on fetal lung function. Analysis of phospholipid and histologic changes is currently under way. (Am J Obstet Gynecol 1986;154:823-30.)

Key words: Oligohydramnios, premature rupture of membranes, fetal growth, pulmonary hypoplasia

The definition of premature rupture of membranes is rupture of the amniotic sac that occurs before the onset of uterine contractions. This complication occurs in approximately 10% of pregnancies at term and in 0.7% to 2.0% of pregnancies before 37 weeks.[1] Although the management of premature rupture of membranes at term usually includes induction of labor, a conservative approach to the management of preterm premature rupture of membranes has been advocated in an attempt to decrease the incidence and severity of neonatal respiratory distress syndrome. Within 24 hours of premature rupture of membranes 80% to 90% of patients can be expected to be in labor.[2] However, when premature rupture of membranes occurs remote from term, a longer latency period can be expected. Mead[3] showed that in preterm pregnancies 20% to 25% of patients were undelivered after 7 days. Taylor and Garite[4] recently reported that in patients with premature rupture of membranes before fetal viability (16 to 25 weeks), 62.3% delivered within 1 week, 71.7% within 2 weeks, and 77.4% within 1 month.

Chorioamnionitis, endomyometritis, and sepsis represent the major maternal risks associated with conservative management. Risk assessment for the fetus includes stillbirth, neonatal infection, respiratory distress, neonatal death, deformation syndrome, and pulmonary hypoplasia. If a conservative approach to the management of preterm premature rupture of membranes is taken and a prolonged latency period occurs, the suspected association between oligohydramnios and lung hypoplasia becomes increasingly important. Normal fetal lung development during pregnancy requires a critical volume of amniotic fluid.[5-6] Neonates delivered from pregnancies complicated by oligohydramnios often have severe pulmonary hypoplasia resulting in early death[3, 7, 8] or evidence of diminished growth.[9] Theoretically, the absence of amniotic fluid allows the uterus to exert continual pressure against the fetus, resulting in abnormal fetal growth and development. The loss of fetal intrapulmonary fluid acting as an internal stenting force provides an additional explanation for pulmonary hypoplasia resulting from preterm premature rupture of membranes.[10] The role of preterm premature rupture of membranes as an effective stimulus to accelerate functional pulmonary maturity in the fetus is controversial. Mead[3] found 14 studies in the literature demonstrating a decreased incidence of respiratory distress syndrome after prolonged premature rupture of membranes and 11 studies unable to show any such association.

To examine the implications of oligohydramnios resulting from premature rupture of membranes, we developed an animal model of chronic amniotic fluid leakage in the fetal rabbit. Our study was designed to in-

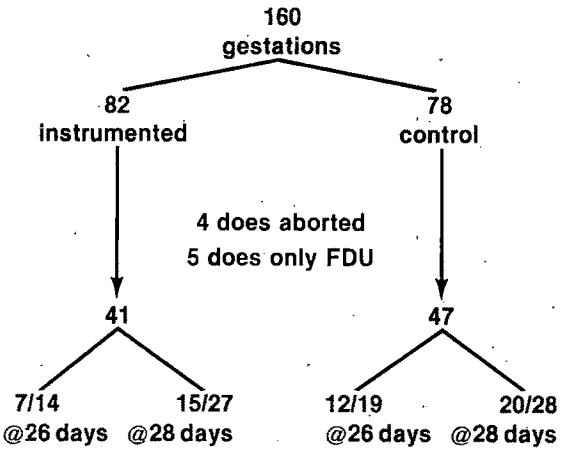

Fig. 1. Fetal loss rate associated with laparotomy and placement of Penrose shunt for chronic amniotic fluid leakage. *FDU*, fetal death in utero.

vestigate the association between oligohydramnios and alterations in fetal growth characteristics. In addition, the reported beneficial effect of premature rupture of membranes on fetal/neonatal lung function was assessed.

Material and methods

Twenty-three time-dated pregnant New Zealand white rabbits were purchased from a local animal breeder. On arrival at the Georgetown Animal Resources Facility on day 20 to 21 of pregnancy, each doe was weighed and housed in a separate cage. Guidelines established by the American Association for Accreditation of Laboratory Animal Care were followed during this study. Commercially available dry rabbit food and fresh water were provided ad libitum. On day 23 of gestation, after an overnight fast, the does were weighed and given an intramuscular injection of ketamine (35 mg/kg) and xylazine (5 mg/kg). After the doe was sedated, the abdomen was shaved and the trachea was visualized and intubated with a 3.0 mm Portex endotracheal tube. Animals were restrained on the operating table and anesthesia was maintained with 1% to 2% halothane in oxygen. After the abdomen was prepared and draped, the uterus was exposed through a midline abdominal incision. The number of fetuses per uterine horn was noted. Hysterotomy and amniotomy were carried out on alternate gestational sacs. The uninstrumented littermates served as controls. Continued drainage of amniotic fluid into the maternal peritoneal cavity was assured by placement of a 2 cm segment of ¼ inch Penrose drain. The hysterotomy was closed with 1 or 2 simple stitches of 4-0 Prolene incorporating the Penrose drain to prevent displacement. The abdomen was closed in layers, and each doe was given 300,000 U of procaine penicillin subcutaneously. The doe was kept warm during recovery from anesthesia and returned to her cage where food and water were again provided.

The pregnancy was allowed to continue until either day 26 or 28, at which time the doe was weighed and sacrificed by intravenous sodium pentobarbital (60 mg/kg). The fetuses were delivered by rapid cesarean section and their tracheas clamped to prevent breathing. Death occurred shortly thereafter. The fetal neck was opened, and the trachea was dissected free. The trachea was opened and cannulated with a 19-guage tubing adaptor tied in place with 3-0 silk. The adaptor was connected to a system previously reported[11] that accurately records air pressure/volume curves. The experimental protocol consisted of inflating each set of lungs to 35 cm of water and maintaining this pressure for 4 minutes to obtain maximum lung volume. Three deflation-inflation cycles were performed at a pressure between 0 and 35 cm of water. Cycling times for each completed loop were between 2 and 4 minutes. In comparing these curves between different fetuses, we chose to analyze only the second inflation and deflation limb. The second loops appeared most reproducible in that they were essentially identical to the third loops. Air volumes were expressed as milliliters of air per kilogram of fetal body weight and milliliters of air per milligram of wet lung weight at maximum lung volume. Proportional volume changes during inflation and deflation were expressed as a percentage of maximum lung volume which was designated as 100%. Lungs that developed air leaks during the pressure/volume studies were eliminated from this phase of analysis.

On completion of the pressure/volume studies, the fetal body, lung, and liver were weighed to 0.001 mg. To standardize the organs to account for differences in body weight, ratios of lung and liver to body weight were calculated.

Two-factor analysis of variance was used to examine the proportional lung volume changes, and the unpaired Student's T test was used for all other statistical analysis; p values <0.05 were considered significant.

Results

Of the 23 does, one was not pregnant and one aborted before the surgical procedure. Following the intramuscular injection, one animal had a respiratory arrest and could not be resuscitated, leaving 20 animals for study. The mean number of fetuses per doe was 7.5 (range 4 to 11). In general, the fetuses were implanted in each uterine horn in equal numbers. Of the 160 fetuses noted at laparotomy on day 23, 82 underwent creation of the amniotic fluid fistula and 78 littermates served as controls. Four does aborted before scheduled cesarean delivery, and five were found to

have only fetal deaths at reexploration. Peritonitis was identified in six does, occurring in 75% (three of four) of those aborting and 60% (three of five) of those having only fetal deaths. Overall, 54 of 160 fetuses (35%) survived until planned cesarean delivery on either day 26 or 28 of gestation. If the does who aborted or had no viable fetuses are discounted, 54 of 88 fetuses (61%) survived until planned delivery. Seven of 14 instrumented fetuses (50%) and 12 of 19 control littermates (63%) were viable at delivery on day 26. Similarly, 15 of 27 instrumented (56%) and 20 of 28 controls (71%) survived until delivery at 28 days (Fig. 1). The continued patency of the amniotic fluid fistula was confirmed by the finding of little or no amniotic fluid when viable instrumented fetuses were delivered.

Amniotomy and maintenance of the amniotic fluid fistula produced significantly smaller fetuses with smaller lungs than those of controls at both 26 and 28 days of gestation (Table I). The lungs were smaller not only by absolute weight but also by lung weight/body weight ratio at 28 days of gestation. No differences in liver weight or liver weight/body weight ratio were discovered on analysis of instrumented and control fetuses at either gestational age. Based on gross inspection, instrumented fetuses appeared to have decreased subcutaneous fat and more translucent skin compared to control fetuses. Three of 22 viable instrumented fetuses (14%) showed evidence of oligohydramnios deformation syndrome. Two fetuses exhibited positional abnormalities of the limbs, and one had mild facial asymmetry.

The maximum lung volume at a transpulmonary pressure of 35 cm of water for both instrumented and control fetuses was the same at 26 days. By 28 days, instrumented fetuses tended to have a smaller lung volume than control fetuses but this difference was not statistically significant (Fig. 2). Standardization of maximum lung volume to fetal body weight revealed no difference at either 26 or 28 days of gestation (Fig. 3). Comparison of maximal lung volume to lung weight at 28 days also failed to show a difference (Fig. 4).

The lung volumes expressed as percentages of maximum lung volume at a transpulmonary pressure of 35 cm of water during inflation were essentially identical for instrumented and control fetuses at both 26 and 28 days. With the mother considered as the random factor, two-factor analysis of variance of the deflation limb revealed no difference at 26 days (Fig. 5). However, percentages of maximum lung volume at a transpulmonary pressure of 35 cm of water during deflation at pressures of 10 cm and 15 cm of water were significantly larger for instrumented fetuses compared to control fetuses at 28 days. Additionally, at a pressure of 0 cm of water there was a tendency for greater residual lung volume (Fig. 6).

Comment

We chose the rabbit as our animal model because of its surgical practicality, multifetal gestation, and the extent of reported data on fetal growth and development available for comparison. The fetal rabbit lung develops through the same stages as the human. The glandular stage is completed at day 24 (human, day 112) with the canalicular stage occurring from day 24 to 27 (human, day 112 to 168). The final intrauterine stage, saccular, takes place between day 27 and term, which for the rabbit is 31 days (human, 280 days). Therefore our study design created chronic amniotic fluid leakage resulting in oligohydramnios extending from late glandular through canalicular into the saccular stage of development. This duration of oligohydramnios should result in pulmonary hypoplasia characterized by inadequate development of pulmonary acini and restricted vascularization. These events would normally

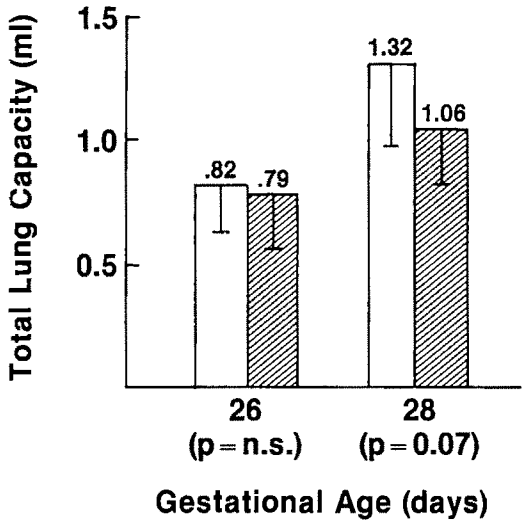

Fig. 2. The maximum lung volume for control *(open bar)* and instrumented *(hatched bar)* fetuses at 26 and 28 days of gestation.

occur during the canalicular stage of development. Human fetuses and neonates with pulmonary hypoplasia from congenital hydronephrosis, prolonged premature rupture of membranes, or diaphragmatic hernia often have pulmonary histologic changes compatible with developmental arrest at 20 weeks' gestation or earlier.[7]

Our studies support the theory that the compressive effects of oligohydramnios inhibit normal fetal body and lung growth. Nakayama et al.[12] have shown similar effects in rabbit fetuses exposed to oligohydramnios from day 24 until term. Other investigators have confirmed a detrimental effect on lung weight from reduction of thoracic volume by either creation of a diaphragmatic hernia[13] or insertion of intrathoracic balloons.[14] Fetal breathing and intrapulmonary fluid are thought to be necessary for normal lung development.[10] While body weight, lung weight, and lung weight/body weight ratio were affected by oligohydramnios, liver weight and liver weight/body weight ratio were unchanged. This finding suggests that umbilical blood flow was not substantially impaired and that uteroplacental insufficiency does not occur following premature rupture of membranes. Wesson et al.[15] have shown that ligation of the fetal rabbit trachea will result in decreased body weight similar to that found in neonates with esophageal or duodenal atresia. Oligohydramnios caused by chronic leakage may deprive the fetus of normal amniotic fluid swallowing and its possible influence on fetal protein metabolism or mucosal enzyme maturation. We recognize that this model does not exactly reproduce the occurrence of premature rupture of membranes in the human. A state of continuous anhydramnios was created by the fistula in contrast to the intermittent loss usually associated with human premature rupture of membranes.

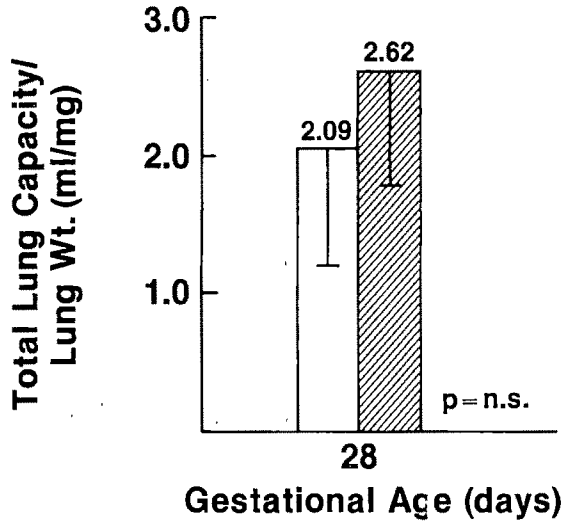

Fig. 4. The maximum lung volume expressed per milligram of wet lung weight at 28 days' gestation.

The pattern of lung weight/body weight ratio for control fetuses is similar to that reported previously[16] with the highest ratio at day 26 and a subsequent decrease at day 28. In our study the ratio followed the normal curve but exhibited a significant difference for instrumented fetuses at day 28. Our belief is that the stress of oligohydramnios has resulted in a stimulus for lung differentiation and depletion of glycogen stores at a significantly faster rate than would normally occur. It has been shown that fetal weight is dependent on uterine horn implantation site.[17] We attempted to negate implantation site bias by instrumenting alternate gestational sacs rather than all pregnancies implanted in a particular uterine horn. We did not correct weight

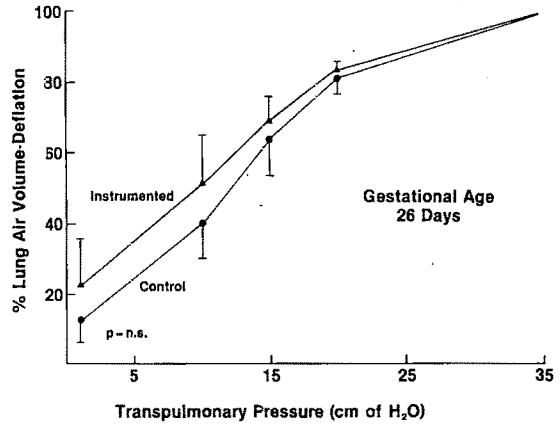

Fig. 5. The proportionate lung volumes expressed as a percentage of total lung volume tended to be higher for instrumented fetuses at 26 days, but these differences were not statistically significant. Mean ± 1 standard deviation shown.

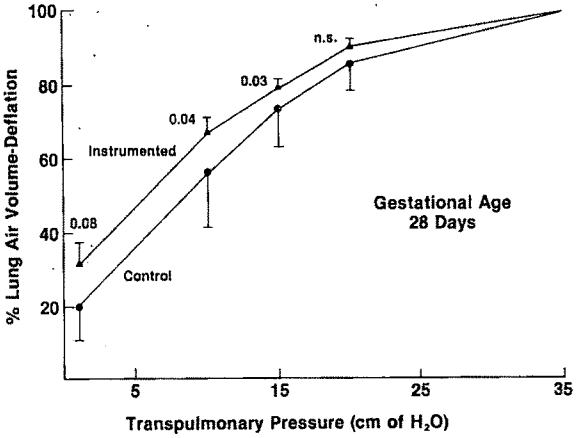

Fig. 6. The proportionate lung volumes at 28 days revealed significantly increased air trapping for instrumented fetuses at 10 cm and 15 cm of water. Mean ± 1 standard deviation shown.

for implantation site, and we assumed random fetal loss at all implantation sites.

We were concerned about the high fetal loss rate. However, we found that as our experience with animal handling, anesthesia, and surgical manipulation improved, our loss rate decreased. Maternal weight loss in the postoperative period did not correlate with fetal loss. Peritonitis developed at random in spite of antibiotic prophylaxis, but when it occurred there was 100% fetal loss. Tocolytic agents were not employed to prevent preterm labor or abortion.

Total lung volume was unchanged at 26 days and showed only a trend toward a decreased lung capacity at 28 days. If thoracic compression alone inhibits development of the acini, then a decrease in lung volume would be expected. Standardization of total lung volume to body weight showed no differences at either gestational age. Since the lung weight/body weight ratio was significantly different at 28 days, the relationship of maximum lung volume to wet lung weight was evaluated. No statistically significant differences were noted; however, the calculated value for instrumented fetuses was higher. One possible explanation is more efficient ventilation of a normal number of acini resulting from a decrease in pulmonary glycogen.

The changes noted during the deflation limb of the pressure/volume studies were the most important findings of our study. There was a trend toward more stable lungs for instrumented fetuses at 26 days, but the differences were not statistically significant. However, at 28 days there was significantly more air trapping in the lungs of instrumented fetuses. These findings indicate not only more stability but also more functional maturity. The exact cause of the improved stability and maturity is unknown. It has been postulated that there is both a decrease in lung connective tissue and an increase in alveolar surfactant.[11] The rate of fetal lung maturation has been shown to be dependent on fetal sex, with females approximately 1.5 days ahead of males.[17] Because of our small numbers, we were unable to separately analyze male and female outcomes.

The absolute risks and benefits of prolonged premature rupture of membranes remain unknown. We have shown both detrimental (weight alterations) and beneficial (improved lung stability) effects of oligohydramnios. It has been reported that the effects of oligohydramnios on body weight and lung weight can be reversed by relieving thoracic compression by infusion of fluid into the uterine cavity.[12] The potential effect of this approach on pressure/volume studies will be examined in the future. Currently we are fractionating lung phospholipids and examining both light and electron microscopic lung sections. We plan to continue our study on a larger basis to examine the effects of fetal sex and uterine implantation site. In addition, we would like to explore the issue of a critical day for the development of pulmonary hypoplasia related to amniotic fluid loss.

We gratefully acknowledge the help of Dr. Susan Ahmed with statistical analysis, Ruth Anne King with surgical assistance, and Richard Rabold with performance of the pressure/volume studies.

Discussion

Dr. Bruce K. Young, New York, New York. Studies of the growth and development of the lung offer insight into the pathogenesis of many important syndromes in perinatal medicine. There are four stages of human fetal lung development: (1) embryonic, from conception to the fifth week; (2) pseudoglandular, from the fifth to the seventeenth week; (3) canalicular, from the sixteenth to the twenty-fourth week; (4) terminal sac period, from the twenty-fourth week to term. By the sixteenth week of gestation, all of the branches of the tracheobronchial tree up to the terminal bronchioles are established, and new branches cannot be formed thereafter. Thus the preacinar airways cannot be increased after this time, and only the gas-exchanging portion, composed of the respiratory bronchioles, alveoli, and alveolar ducts, will differentiate after about 16 to 20 weeks of gestation. Therefore an insult to lung development during fetal life will have different pathologic effects, depending on when it occurs. Further, there are many causes of pulmonary hypoplasia in the human fetus, and their effects are variable, depending on the time of onset and duration during fetal life. These include renal agenesis and dysplasia, urethral obstruction, phrenic nerve agenesis, thoracic dystrophy, diaphragmatic hernia, Rh isoimmunization, polyhydramnios, and premature rupture of membranes, the basis for the present study.[1-3]

Premature rupture of membranes of the human fetus associated with prolonged oligohydramnios has been shown to produce pulmonary hypoplasia and anatomic deformities, particularly when present before the twenty-sixth week of gestation, and when the duration of rupture is >5 weeks.[3,4] Thus, an animal model would be very helpful in determining the pathophysiology, and in formulating any possible plan of therapy. Dr. King and his associates chose a well-described model, the rabbit with amniotic fistula, to study the effects of oligohydramnios on fetal growth and lung development.[5,6] Their data demonstrate statistically significant reductions in birth weight and lung weight in the fetuses subjected to oligohydramnios compared to the control fetuses. This was true for both 26-day and 28-day animals. The ratio of lung weight to birth weight, an index of specific pulmonary hypoplasia, was lower in the 28-day animals with amniotic shunt, with statistical difference at the 0.02 level. Another observation of interest was the 14% incidence of deformation syndrome in the rabbit fetuses with amniotic shunting. Finally, the lung volume studies revealed no difference in maximum lung volume or the ratio of maximum lung volume to body weight. However, in the 28-day animals the percentage of maximum lung volume at deflation with use of pressures of 10 cm and 15 cm of water was greater for shunted lungs, indicating air trapping. The authors state that this indicates not only more stability but more functional maturity. These very interesting observations lead to a number of specific questions.

1. Did the authors make any measurements of amniotic fluid in the shunted and control animals?

2. Since there is a relationship between implantation site and weight, did the authors consider using the contralateral horn fetuses as controls for this confounding variable?

3. At 26 and 28 days there was no difference in lung volume between the shunted and control animals. Since it is recognized that inhibition of fetal breathing by cord transection will induce lung hypoplasia, and this is preventable by tracheal ligation in the rabbit, would the authors consider that a lower intrapulmonary pressure might be more important than compressive effects, since one would expect that compression would reduce the lung volume[7,8]?

4. Why was air trapping seen at pressures 10 and 15 cm of water, but not at the other transpulmonary pressures studied?

5. Would the authors agree that the changes observed during the deflation studies are also consistent with decreased lung connective tissue recoil, as well as with hyperinflation air trapping, as seen with erythroblastosis, until their histologic and biochemical evidence of lung maturity is forthcoming?

Dr. King and his colleagues have presented important work. Oligohydramnios is associated with abnormal pulmonary growth and development in a variety of clinical conditions, for which we have no standard treatments. The authors have addressed the pathophysiologic conditions in a careful study, which has given us the glimmerings of understanding the clinical problem. Further studies addressing the anatomy, histology, and biochemistry of the lungs in this animal model are likely to elucidate the role of oligohydramnios in pulmonary hypoplasia.

DR. CHARLES E. FLOWERS, Birmingham, Alabama. I would like to point out two things.

There is a tremendous reduction in the volume of amniotic fluid during the last 3 days of rabbit gestation. Therefore one must be careful to study through appropriate transmission electron microscopy and enzymatic studies the growth of lung tissue in the shunted animals and the normal rabbits during the twenty-seventh to the thirtieth day of normal gestation.

Second, you have adversely affected uterine blood flow by putting in these uterine shunts. It therefore becomes very important to compare the pups in the contralateral horn, since the shunts can affect uterine blood flow and pulmonary growth.

DR. CHARLES A. WHITE, New Orleans, Louisiana. Dr. King has presented some interesting observations that I presume many of us would like to eventually translate to the solution of clinical problems involving the infants in cases of protracted periods of ruptured membranes.

We do on occasion see these cases and are concerned about the so-called "stiff lung" or the reduced ability of the neonates to adjust to extrauterine respiratory efforts.

Now that Dr. King and his colleagues have established this animal model, do you see merit in extending your studies to allow these treated fetuses to attempt an extrauterine life, allowing them to be delivered either by section-hysterotomy or by natural birth to determine their ability to establish ventilatory efforts as compared to the control animals? That might give us more comparative data to assist in these problems in humans.

DR. KING (closing). Dr. Young's first question was, Did the authors make any measurements of amniotic fluid volume in the shunted and control animals?

No, we did not do that. This had been done previously by Nakayama et al., whose model we patterned ours after, and they could show a statistically significant difference with no fluid in the instrumented gestation and normal amniotic fluid volume in the control gestations.

We did not feel it was necessary to repeat that phase of their study.

The next question was in relationship between implantation site and weight. Did the authors consider using contralateral horn fetuses?

Again, we patterned our studies after Nakayama et al., who did use the contralateral horn. During the preliminary phase of this study I found that the gestations were not equally distributed for some reason. Therefore, to try to eliminate the bias of having only two gestations on one horn and seven or eight on the other, we decided we would alternate our instrumented and controlled gestations.

We realize that this may exert some compression of amniotic fluid or uteroplacental blood flow in the adjacent gestational sacs, but we felt that this would eliminate the bias of horn implantation site.

The next question had to do with tracheal ligation and lower intrapulmonary pressure. Those are true comments, and it has indeed been shown that intrapulmonary pressure is very important. There have been some studies in the past in which tracheal fluid has been continually aspirated from the trachea and pulmonary hypoplasia has been demonstrated.

The next question was, Why was air trapping seen at pressures of 10 and 15 cm of water and not at the other transpulmonary pressure studies?

Our thought is that it probably will be seen with continuing gestation and although we could show no difference at 26 days, by 28 days at 15 and 10 cm there was statistically significant difference, and at 0 cm there was an elevation though not statistically significant. Our feelings are that if this model is continued to 30 or 31 days, we may see a further separation between the instrumented gestations and the control ones.

Would the authors agree that the changes observed during deflation studies were also consistent with decreased lung tissue recoil? Yes, I think that is one of our primary theories.

I can give you some preliminary results on the biochemical and electron microscopic examination.

We could find no difference in total phospholipids in the instrumented animals compared to the control

ones. We are currently fractionating those phospholipids, so we will have some additional data in the future.

With regard to the electron microscopic examination, there is no question that the appearance of the lamellar bodies in the type II alveolar cells in the twenty-sixth day and twenty-eighth day animals were more numerous in the instrumented animals. In addition, the lamellar body appears to be a denser lamellar body at the twenty-sixth day after only 3 days of induced oligohydramnios. At this point we do not have a way to quantify the amount of this production, but we will do that in the future.

Regarding Dr. Flower's question about the last three days of gestation, we would agree that continuation through term and even continuing on, as has been suggested by Dr. White, would be important to learn how these animals tolerate labor, delivery, and early newborn existence. We plan to continue with these studies and will investigate those problems.

Temporal and receptor correlates of the estrogen response in sheep

Frank C. Greiss, Jr., M.D., James C. Rose, Ph.D., Timothy E. Kute, Ph.D., Randall T. Kelly, M.D., and Lisa S. Winkler, B.S.

Winston-Salem, North Carolina

Uterine blood flow and uterine cytosol and nuclear estrogen receptors were measured at critical times during estradiol-induced vasodilatation in acute anesthetized and chronic conscious sheep preparations at estradiol bolus injection frequencies from 1 to 24 hours. During acute experiments, the uterine blood flow response was muted and cytosol estrogen receptor replenishment did not occur whereas full replenishment occurred in 12 hours in conscious ewes. In ewes treated with daily estradiol that had a stable daily uterine blood flow response, the uterine blood flow response 24 hours after uterine biopsy was similar to the preoperative one. Analysis of the duration of peak uterine blood flow levels and the rate of uterine blood flow descent from peak levels showed that an interval of 18 hours between estradiol injections was necessary for the uterine blood flow response to approximate that observed after 24 hours. These observations suggest: (1) that uterine vascular receptor replenishment is delayed compared with that of the total uterus; (2) that operative stress compromises cytosol estrogen receptor metabolism and possibly nuclear estrogen receptor function; (3) that the delayed maximum uterine blood flow response to estradiol in ewes previously untreated with estradiol is due to a trophic uterine effect of daily estradiol stimulation. (AM J OBSTET GYNECOL 1986;154:831-8.)

Key words: Uterine blood flow, estrogen, estrogen receptors, uterine vasodilatation

The uterine blood flow response to estrogenic stimulation has been studied extensively in the oophorectomized ewe. When estradiol-17β is injected intravascularly, uterine blood flow is unchanged for 30 minutes. Then a progressive marked increase occurs and reaches peak levels after 1.5 to 2.0 hours. Thereafter, uterine blood flow gradually declines to control levels during 12 to 18 hours.[1] This response can be duplicated daily. Dose-response curves indicate that the maximum response occurs from 1 μg/kg given intravenously, 0.5 μg/kg intra-arterially, or 0.5 to 1.0 μg given directly into the uterine artery.[2, 3] If the estradiol injection is given during a continuous infusion of cycloheximide into the uterine artery, the response is ablated.[1] This observation and the latent phase before the increase in uterine blood flow have been interpreted to indicate that estradiol induces the formation of a vasodilator substance that mediates the vascular response. Although substances have been identified that can cause a response quantitatively similar to that of estradiol, none of these has been shown to be the mediator per se. One other characteristic of the uterine blood flow response is pertinent. At ovine estrus, uterine blood flow increases from very low preestrous levels to about half of those observed after maximum doses of estradiol, and these levels are maintained for 24 hours or more.[4] Presumably, the uterine blood flow rise is caused by and lags about 6 hours behind a similar curve of estradiol secretion. However, in our laboratory and in experiments reported to date, a sustained increase in uterine blood flow has never been induced by exogenous estradiol administration except when the estradiol is given intramuscularly in oil. In fact, when estradiol is infused continuously at maximum pharmacologic doses, the uterine blood flow response is no different from that after a single injection.[2] These observations suggest that when maximum pharmacologic doses of estradiol are given, a refractory phase occurs, which may be related to the metabolism of uterine estrogen receptors. To test this hypothesis, we have measured cytosol and nuclear receptors in serial uterine biopsy specimens obtained at critical times during the uterine blood flow response to estradiol in acute and chronic experiments in sheep. In addition, further knowledge of the refractory period has been achieved in conscious ewes by observation of the uterine blood flow response to various frequencies of intermittent estradiol injections.

Methods

Animal preparations

Group 1. In a preliminary group of two ewes anesthetized with pentobarbital sodium, biopsy specimens were obtained from the upper, middle, and lower thirds of the uterine horn and the animals were put to death. The biopsy specimens were analyzed for cytosol estrogen receptor content.

Group 2. Nonpregnant multiparous ewes were anesthetized with intravenous ketamine and supplemental pentobarbital sodium when necessary. Bilateral oophorectomy, implantation of an electromagnetic flow probe around the left middle uterine artery, and implantation of an aortic occlusion back loop were performed as previously described.[5, 6] Two catheters were threaded via the mammary artery and vein into the descending aorta and inferior vena cava for blood pressure monitoring and estradiol injections. After the ewes recovered from operation, daily intravenous bolus injections of estradiol, 1 μg/kg, prepared after the method of Killam et al.[1] were given and uterine blood flow was monitored until similar daily flow peaks occurred. Then a uterine biopsy specimen from the horn contralateral to the flow probe was obtained at laparotomy with the animal under ketamine anesthesia 24 hours after the previous estradiol injection. On recovery, daily estradiol doses were continued for 4 to 7 days. Then repeat uterine biopsy specimens were obtained in different animals 6, 12, and 18 hours after the last estradiol injection. Then the ewes were put to death. In a subset of this group biopsy specimens were obtained 24 hours after a previous biopsy and estradiol injection.

Uterine blood flow responses were analyzed as in group 4 described below and uterine biopsy specimens were analyzed for cytosol estrogen receptor and compared by means of analysis of variance and two-tailed Student's *t* test.

Group 3. Ewes were prepared as in group 2 and after repetitive daily estradiol-induced uterine blood flow peaks occurred, the following acute experiments were performed 24 to 27 hours after the preceding estradiol injection.

Ewes were paralyzed with curare, intubated while under topical anesthesia, and anesthetized with a 2:1 mixture of nitrous oxide–oxygen. The rate and frequency of respirations were adjusted by a Harvard small animal respirator to maintain normal pH and blood gas levels. Supplemental curare was used as needed throughout the experiment. When uterine blood flow and maternal blood pressure were stable, the uterus was exposed via a midline incision and a control biopsy specimen (1 to 2 gm) from the uterine horn contralateral to the flow probe was obtained. Then an intravenous bolus of estradiol, 1 μg/kg, was given. Repeat uterine biopsy specimens were obtained 5 and 30 minutes and 2, 6, 10, 14, and 18 hours later and the ewes were put to death. Between biopsies, the abdomen was closed to minimize trauma. Biopsy specimens were analyzed for cytosol estrogen receptor and nuclear estrogen receptors as described below. Since cytosol estrogen receptor depletions were similar to those observed in conscious ewes (group 2), control experiments to exclude an effect of operative stress were not performed.

Group 4. In a final group of ewes chronically prepared as in group 2, after daily estradiol-induced uterine blood flow peaks occurred, uterine blood flow responses were observed after the following regimens of intravenous estradiol, 1 μg/kg, bolus injections: every hour for eight doses, every 2 hours for five doses, every 3 hours for four doses, every 4 hours for three doses, and every 6 hours for three doses. Further responses were observed after estradiol given 8, 10, 12, 14, 16, and 18 hours after the preceding estradiol dose. The various estradiol administration regimens were randomized so as to minimize the possible effect of time from initial operation on the observed responses. Five 1-minute uterine blood flow levels were averaged every half hour during response periods and results were expressed as a percentage of the maximum flow observed during each individual response. Intraresponse levels at the various dose frequencies were compared after 4 hours with those of the 24-hour dose frequency by means of analysis of variance and the Mann-Whitney test for multiple comparisons.

Cytosol receptor assay

Preparation of cytosol. The cytosol fractions were prepared by the method of Anderson et al.[7] All procedures were done at 4° C unless otherwise stated. Approximately 0.5 gm of frozen tissue was weighed out and minced into small fragments with a scalpel. The minced tissue was put in a Kontes glass grinder along with 2 ml of buffer A (10 mmol/L Tris, 1.5 mmol/L ethylenediaminetetraacetic acid, 10% glycerol, and 1.0 mmol/L monothioglycerol, pH 7.4 to 7.5) and homogenized. After the homogenate was transferred to a centrifuge tube, another 4 ml of buffer was added. The suspension was centrifuged at 1000 × g for 10 minutes to separate the nuclear and cytosolic fractions. The cytosolic fraction was mixed on a vortex mixer with a dextran-coated charcoal pellet (6 ml of 1.0% Norit A and 0.5% dextran) to remove endogenous estradiol and incubated for 10 minutes at 0° C. After the incubation period, the suspension was centrifuged at 120,000 × g for 30 minutes. The supernatant protein was measured by the Waddell method and normalized to 2 mg/ml for the binding study.

Cytosolic binding assay. The cytosol fraction was used in binding studies done by Scatchard analysis[8] and the assay of Katzenellenbogen et al.[9] The Scatchard analysis uses 10 points with doses of tritiated estradiol varying

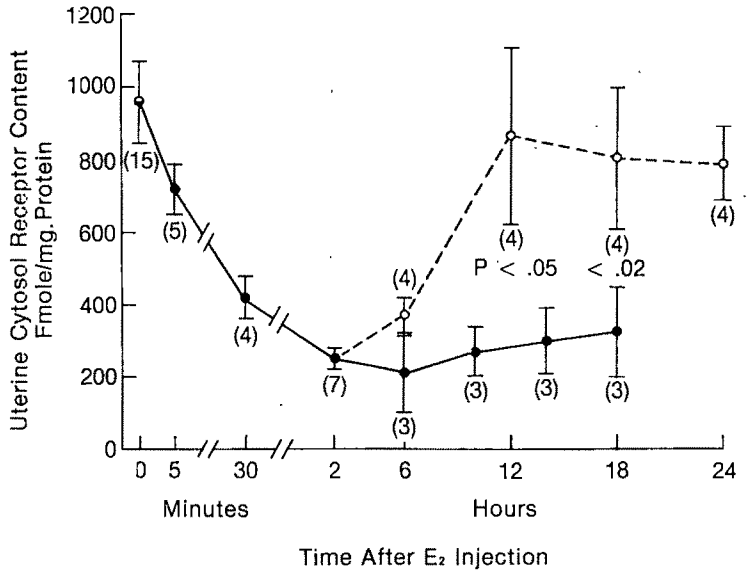

Fig. 1. Uterine cytosol estrogen receptor content (mean ± SEM) after intravenous estradiol injection (1 μg/kg) in continuously anesthetized (●) and previously conscious (○) ewes. *Numbers in parentheses* indicate number of observations.

from 0.1 to 10 nmol ± 5×10^{-7} mol/L DES. The addition of DES is to correct for nonspecific binding. In the case of Scatchard analysis, the specific binding is defined as the total binding of receptors minus the nonspecific binding of receptors. The reactions were stopped with dextran-coated charcoal and analyzed by a computer program.[10]

The assay of Katzenellenbogen et al., which determined total binding in the cytosol, uses triplicates of 10 nmol/L tritiated estradiol ± 10×10^{-7} mol/L DES. Cytosol was added to each vial and incubated for 1 hour at 0° C, then at 30° C for 18 hours. The reactions were then cooled to 0° C and stopped with dextran-coated charcoal. The calculations for the specific binding in this case were based on total binding minus nonspecific binding divided by the total protein concentration and reaction volume.

Nuclear binding assay. The nuclear fraction was assayed by the method described by Anderson et at.[7] The nuclear suspension was vigorously mixed on a vortex and 0.25 ml aliquots were transferred into two tubes containing 13 nmol/L tritiated estradiol and two tubes containing 13 nmol/L tritiated estradiol + 13×10^{-7} mol/L estradiol. To each tube 0.25 ml of buffer was added and mixed on a vortex. These reactions were incubated in a 37° C shaking warm water bath for 1 hour. Then to remove any free steroid the reactions were washed three times with 1 ml of buffer A and centrifuged at 1000 × g for 10 minutes. The supernatant was discarded and the nuclear pellet resuspended in 1.0 ml of ethanol and incubated for 30 minutes at 30° C. Aliquots of 0.3 ml were taken from each tube and counted. The specific nuclear binding activity was calculated in femtomoles per gram of tissue and femtomoles per milligram of deoxyribonucleic acid (DNA).[11]

Results

Estrogen receptor responses. Cytosol estrogen receptor content in three different parts of the uterine horn were determined in two control ewes (group 1). These distributions are shown in Table I and indicate that receptor content in different areas of the ovine uterus is similar.

Uterine cytosol estrogen receptor responses were measured by analysis of specimens from timed biopsies during 18 hours in five anesthetized ewes (group 3). Complete results were obtained in only three ewes. Within 30 minutes of the estradiol bolus injection, cytosol estrogen receptor receptors decreased 57% from control, reached a nadir 75% below control levels after 2 hours, and stayed at this level for the remainder of the observation time (Fig. 1, *closed circles*).

The time course of cytosol estrogen receptor replenishment in 10 ewes 2 to 10 days after prior operation and 6, 12, and 18 hours after estradiol injection are

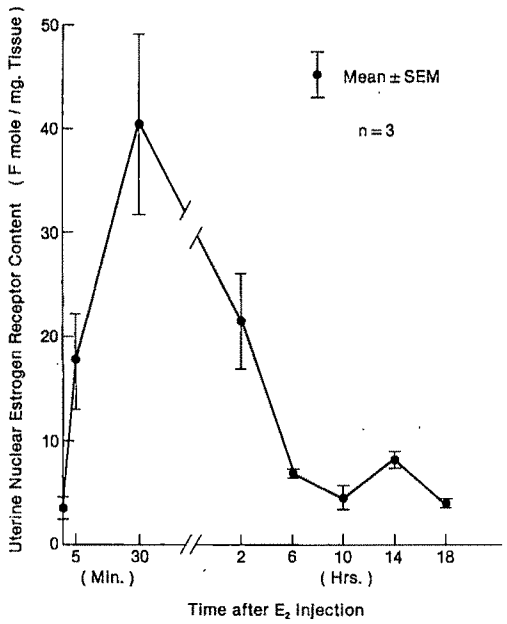

Fig. 2. Uterine nuclear estrogen receptor content after intravenous estradiol injection (1 μg/kg) in continuously anesthetized ewes.

also shown in Fig. 1 *(open circles)*. The four assays at 24 hours were obtained 24 hours after a previous biopsy and estradiol injection.

Uterine nuclear estrogen receptor responses during 18 hours in three of the anesthetized ewes (group 3) are shown in Fig. 2. The nuclear estrogen receptor levels peaked 30 minutes after the estradiol injection and rapidly decreased to control levels within 6 hours.

Uterine blood flow responses. In four of the five ewes monitored before and during uterine biopsies while under anesthesia (group 3), the typical uterine blood flow response after estradiol occurred. However, the magnitude of the response was markedly reduced and achieved less than 50% of that evoked 24 hours earlier in the conscious state. In the one ewe in which no uterine blood flow response occurred, the cytosol estrogen receptor responses were similar to those in the other ewes.

During daily recordings of uterine blood flow responses before and 24 hours after uterine biopsies in ewes in group 2, it was noted that peak uterine blood flow levels were approximately the same as those observed during the days preceding the biopsy. These are shown in Table II.

Eighty-six regimens of bolus doses of estradiol at varying hourly frequencies were administered to nine ewes. Composite uterine blood flow responses at 1-, 2-, 3-, 4-, and 6-hour dose frequencies are illustrated in Fig. 3. *Panel 1* shows the uterine blood flow response during hourly estradiol doses during 8 hours and the control response after 24 hours. Except for a more

gradual descent of uterine blood flow from peak levels, the hourly dose response was similar to the 24-hour one. When estradiol was administered every 2 hours (*panel 2*, Fig. 3), the maximum response was reachieved 1 hour after the second dose but further doses only muted the waning response or caused a minimal uterine blood flow increase. Administrations every 3 hours (*panel 3*, Fig. 3) caused muted uterine blood flow increases 1 to 1½ hours later but failed to alter the progressive descent from the maximum uterine blood flow levels induced by the first dose. When estradiol was administered every 4 hours (*panel 4*, Fig. 3), peak flow rates recurred transiently after the second dose but only a muted rise occurred after the third dose. It was not until estradiol was administered every 6 hours (*panel 5*, Fig. 3) that uterine blood flow peaks equal to those induced by the first dose could be reinduced regularly. However, the duration of the peak responses was shorter and the rate of uterine blood flow descent from peak levels was more rapid than after the first dose.

The uterine blood flow rates after estradiol injections timed 6, 8, 10, 12, 14, 16, 18, and 24 hours after the previous injection are illustrated in Fig. 4. As the estradiol dose interval increased, the rate of uterine blood flow descent from peak levels became slower and the sustained uterine blood flow rate between 1.5 and 2 hours reappeared. At the 18-hour dose frequency, although the uterine blood flow rates after 4 hours were slightly lower than the 24-hour ones, they were not significantly different whereas those at dose frequencies between 6 and 16 hours were different ($p < 0.02$).

Comment

Current steroid response theory indicates that a given response is dependent on the quantity of steroid exposed to a cell and the concentration of steroid-specific macromolecule receptors present in the cytosol of target cells. Upon formation of the steroid-receptor complex, it is translocated to the cell nucleus (nuclear receptor) where transcriptional events begin the process of effecting the various actions of the steroid. Since the initial concentration of cytosol receptor controls the

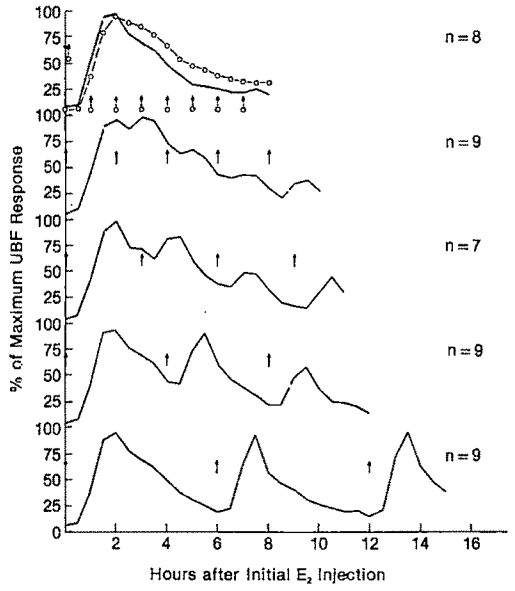

Fig. 3. Uterine blood flow responses after intravenous estradiol injections (1 μg/kg) (↑) at different injection frequencies. *Upper panel* compares 24-hour dose frequency *(solid line)* with hourly dose frequencies (♂ and o——o).

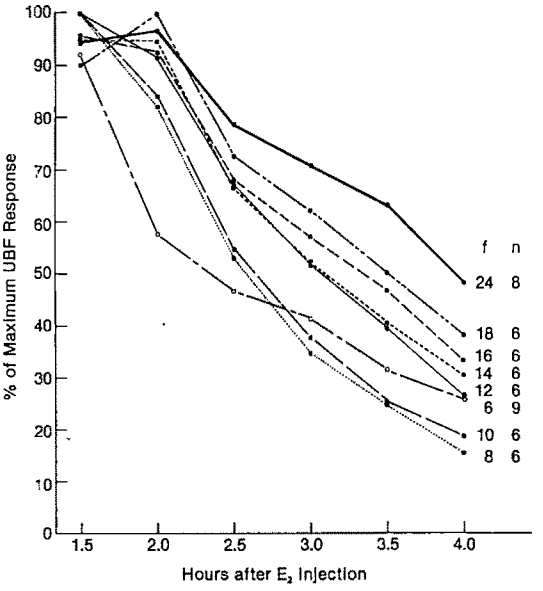

Fig. 4. Uterine blood flow responses after intravenous estradiol injections (1 μg/kg) at dose frequencies *(f)* between 6 and 24 hours. All of the responses at 4.0 hours are different from the 24-hour response ($p < 0.02$) except that after 18 hours.

nuclear receptor, a depletion of cytosol receptor will occur with translocation and the process of cytosol receptor replenishment must occur. Until a sufficient amount of cytosol receptor is replenished, the steroid-induced response will be blunted or erased depending on the degree of cytosol receptor depletion induced by the dose of administered steroid. This highly simplified description of a complex process provides the basis for using a continuously monitorable response to estradiol stimulation, uterine vasodilatation, to identify critical times for uterine biopsies for cytosol estrogen receptor assay and possibly to permit the response itself to give insight into cytosol estrogen receptor replenishment. We appreciated at the outset that cytosol estrogen receptor and nuclear estrogen receptor responses of samples of entire uterine tissues may not reflect those of the uterine vasculature but felt that such responses in the light of uterine blood flow changes may complement interpretation of responses. Since cytosol estrogen receptor contents were similar in different parts of the uterine horn, we felt that multiple biopsies from differing parts of the horn provided valid data for comparison.

It is clear from Fig. 1 that the intravenous dose of estradiol necessary to evoke maximal uterine vasodilatation uses only 75% of available total uterine cytosol estrogen receptor. The uterine blood flow responses during injections of estradiol every hour and every 2 hours (Fig. 3) suggest that similar incomplete depletions in the cytosol estrogen receptor of the uterine vasculature occur; that is, since the period of maximal dilatation can be prolonged or regained during the time of maximal initial depletion of cytosol estrogen receptor, it is likely that such responses are mediated by residual cytosol estrogen receptor. It would follow that recurrent uterine blood flow elevations after estradiol injections given 3, 4, and 6 hours after the initial injection would reflect the sum of residual and replenished cytosol estrogen receptor. In conscious unstressed ewes, cytosol estrogen receptor replenishment occurred within 12 hours of estradiol administration. These results are consistent with those reported in rat uteri by Clark and Peck.[12] However, the uterine blood flow responses suggest that cytosol estrogen receptor replenishment in the uterine vasculature proceeds at a slower pace than that in the uterus as a whole. For example, repetitive uterine blood flow peak flows could not be induced by estradiol until 6 hours after the preceding estradiol injection, a time when total uterine cytosol estrogen receptor replenishment was 39% of control. However, these peak flows were dissimilar from 24-hour controls in that the duration of the response was much shorter. This led us to look at the vasodilatory response from two aspects, its absolute magnitude and its magnitude over time. Methodologic limitations dictated the 4-hour observation period. Since duplication of uterine blood flow levels observed 24 hours after a preceding estradiol injection required an 18-hour interval, we have interpreted this to indicate that vascular cytosol estrogen receptor replenishment sufficient to duplicate control levels requires at least 18 hours. A longer time to full replenishment cannot be

excluded, however, since the control response was achieved presumably with <100% of available cytosol estrogen receptor.

Investigators in this area have observed regularly that in animals under anesthesia, the estradiol vasodilatory response is muted and that after initial oophorectomy and flow probe implantation in ewes previously untreated with estradiol, at least 3 to 4 days of daily injections of estradiol is required to evoke a maximum repetitive uterine blood flow response. Anecdotally, both observations have been attributed to operative stress. This might be a function of operative and postoperative physiologic responses not only of the cardiovascular system but of estrogen receptor function as well. The present observations give possible insight into the explanations for these responses. Clearly, operative stress (anesthesia and operation) exerts immediate effects. In every case, the magnitude of the uterine blood flow response was blunted in comparison with responses in conscious unstressed animals and cytosol estrogen receptor replenishment did not occur (Fig. 1). Alternately uterine nuclear estrogen receptor responses were similar to those previously reported in rats.[12] Since cytosol estrogen receptor replenishment was obviously altered, it is possible that, although receptor translocation occurred normally, posttranslocational events were similarly compromised. Such an interpretation is supported by the observations of Lippe and Szego,[13] who determined that the suppressive effect of actinomycin D on estrogen-induced uterine water imbibition is mediated by adrenocortical hyperactivity.

Twenty-four hours after uterine horn biopsy, cytosol estrogen receptor replenishment was apparently complete and when repetitive daily estradiol responses had been achieved before operation, uterine blood flow responses 24 hours later approximated the preoperative ones (Table II). We believe that uterine horn biopsy is at least as stressful as oophorectomy and implantation of a flow probe on the middle uterine artery. If this is true, then the initial low uterine blood flow levels observed after the latter procedure cannot be attributed to a prolonged effect on uterine estrogen receptor metabolism. Rather it would appear that late uterotropic responses (cellular hypertrophy and hyperplasia) permit a progressively greater uterine blood flow response to daily estradiol stimulation that would appear to maximize after 4 to 7 days.

The results presented herein further clarify events of the estradiol-induced vasodilatory response of the ovine uterus. Since most investigators of the estradiol-induced uterotropic responses address themselves to early and late metabolic and biosynthetic responses, we hoped that a continuously monitorable response might improve our understanding in this area. The observed results are consistent with known steroid-receptor interaction theory but the significance of the observations is only speculative because methodologic limitations preclude actual measurement of cytosol estrogen receptor and nuclear estrogen receptor in the uterine vasculature.

Discussion

Dr. Edgar L. Makowski, Denver, Colorado. Since the observation by Markee[1] that uterine blood vessels become dilated after the administration of estrogens, many investigators have been interested in the steroid stimulus—uterine response relationship In the current study by Greiss and his associates, this relationship was investigated in nonpregnant, oophorectomized sheep by monitoring uterine blood flow and uterine cytosol and nuclear receptors during estradiol-induced vasodilatation. Changes in uterine blood flow were determined by electromagnetic flow probes, and alterations of uterine receptors (cystosol and nuclear) were interpreted according to the classical "two-step" biochemical model of intracellular hormonal interaction.[2] This model hypothesizes that the steroid binds with a soluble receptor in the cytoplasm of target cells The receptor-hormone complex is then translocated to the nucleus

in a temperature-dependent process and there interacts with the nuclear chromatin. This interaction initiates transcription and new protein is synthesized.

In group 1 of the current study, consisting of two animals, uterine biopsy specimens from various portions of the horn were analyzed for cytosol estrogen receptor content. The distribution of these receptors was somewhat similar within the same animal but very dissimilar between animals (see Table I). The first question to the authors is: Was the large difference between animals due to differences in the phase of the estrous cycle? Further, it is not apparent from the manuscript if the uterine tissue biopsy specimens were controlled for the presence, number, and size of caruncles. With the "two-step" steroid biochemical model a temporal relationship was demonstrated between the type of receptors and the classical physiologic response to estrogen stimulation. During acute experiments, as in group 2, the investigators noted a blunted uterine blood flow response to the administration of estradiol, which confirms previous results of Killam et al.[3] A new dimension was added to this observation in that uterine cytosol receptor content continued at low levels for the duration of exposure to stress.

Both groups 2 and 3 received estradiol for 4 to 7 days before the acute experiments. However, there was a difference in time of uterine blood flow measurement between the groups. In group 2 the uterine blood flow was blunted during acute experiments, and in group 3 uterine blood flow response 24 hours after the experiments approximated the preoperative levels. The authors speculate that the latter observation could have been secondary to a uterotropic response after the estradiol administration. This hypothesis would have been strengthened if they had included some observations on uterine blood flow in group 3 at the time of uterine biopsies or in group 2, 24 hours after uterine biopsies. Another question for the authors is whether they have any evidence that the estrogen affinity of receptors in the vascular wall is similar to that of those located extravascularly in the myoendometrium.

In group 4, the authors confirm and expand the previous observations of Clewell et al.[4] that the uterine response depends on the arterial concentration of the steroid and the duration as well as pattern of exposure to estrogen. Indeed, a continuous infusion of estrogen at high doses can result in tachyphylaxis.

As noted earlier, the observations of Greiss et al. on the changes of uterine receptors after estradiol administration are based on the "two-step" biochemical model. Recently the validity of this model has been challenged by Welshons et al.[5] and King and Greene.[6] In the elegant immunocytochemical studies of King and Greene, monoclonal antibodies to estrogen receptor protein were developed. Use of such antibodies in experiments on estrogen-sensitive tissues from humans and nonhumans demonstrated that specific staining occurred only in the nuclei of all stained cells. Their results indicate that the in vivo estrogen receptors are localized in the nucleus. These findings are consistent with the observations reported for vitamin D and thyroid hormone receptors.[7-9] Presence of receptors in cytosol may therefore result from redistribution after homogenization of the cells. Welshons et al. examined the distribution of unbound estrogen receptors in GH_3 cells obtained from rat pituitary tumors. Cytoplast and nucleoplast fractions were obtained from these cells by enucleation with the use of cytochalasin B. By this method, most of the unbound estrogen receptors were associated with the nuclear fraction and little estrogen binding activity was present in the cytoplast. These data alter somewhat the biochemical model that assigns free estrogen receptors to the cytoplasm. In light of these recent findings, one must be very cautious in interpreting the role of estrogen receptors. If further investigation verifies the newer observations, the "two-step" biochemical model will certainly require reinterpretation.

Finally, the authors should be commended for their continued interest in attempting to define the mechanism(s) responsible for the induction of uterine vasodilatation after estrogen administration.

DR. NORMAN F. GANT, JR., Dallas, Texas. Dr. Greiss, I wonder if there is not another possible explanation.

I am sure you are familiar with the work of Jim Roberts and the fact that adrenergic receptors are increased or decreased, both α-receptors and β-receptors, based on estrogen versus estrogen-progesterone ratios.

Have you looked at or are you planning to look at adrenergic receptors in uterine or vascular smooth muscle in response to estrogen injection or after the stress of anesthesia?

DR. ARTHUR L. HERBST, Chicago, Illinois. I have a question and a comment about the receptors. As Dr. Makowski mentioned, with immunohistologic techniques, the receptors seem to be primarily in the nu-

cleus. This is true also in human tissues such as endometrial carcinoma and ovarian carcinomas.

Some of the data that we have from our institution would suggest, however, that although they are nuclear in location, their quantitation parallels the biochemical measurement. So, when you speak of "cytosol" receptors, you are probably speaking of loosely bound nuclear receptors. Thus the theory of the steroid-receptor interaction eventually leading to ribonucleic acid–mediated protein synthesis would probably still be valid although the name cytosol is probably not valid.

I just would be interested to know if you have done any immunohistologic studies and if the location of the receptor is also nuclear in your preparation?

Dr. Greiss (Closing). For one of my articles, three discussants is somewhat of a record. In particular, I want to thank Dr. Makowski who, in his usual incisive and complete manner, criticized the paper from exactly the same areas I would have myself.

Dr. Makowski, with respect to the variation in the concentration of estradiol receptors, we did not know where the two animals selected were in the cycle. This was unimportant since we were just trying to see whether distributions were similar. However, in the subsequent experiments, all of the ewes were oophorectomized and had been receiving daily estrogen. Despite this there remained very large baseline variations in estradiol receptor concentrations that I am at a loss to explain. These variations, however, account for the wide variations you have seen in the data.

We made no attempt to evaluate receptor content in the caruncles alone.

With respect to the vascular affinity of estrogen as compared to that of the rest of the uterus, to my knowledge there are no data available and this is one of the things that we are speculating about.

I appreciated very much Dr. Herbst's comments because he answered what I would answer in terms of the two-step method versus the newer total nuclear receptor concept. Actually, what we have called cytosol receptors may not actually be in the cytosol, but in terms of interpretation the two-step model seems to be a useful working concept at this point. We must, however, recognize that so-called cytosol receptors indeed may be in the nucleus. We have not done any immunohistologic studies along this line.

Dr. Gant, we have not measured any adrenergic receptors during these studies but I would doubt that they changed significantly since β-adrenergic blockage has minimal effect on the estrogen response.

Histologic and hormonal documentation of the luteinized unruptured follicle syndrome

Robert S. Schenken, M.D., Lawrence B. Werlin, M.D., Robert F. Williams, Ph.D., Thomas J. Prihoda, Ph.D., and Gary D. Hodgen, Ph.D.

San Antonio, Texas, and Bethesda, Maryland

Histologic and hormonal documentation of a luteinized unruptured follicle that occurred during a spontaneous menstrual cycle in a rhesus monkey is presented. Frequent (every 2 hours) blood sampling to assess midcycle hormonal dynamics in the monkey with the luteinized unruptured follicle and in five monkeys with an ovulatory stigma revealed significant aberrations in the gonadotropin and steroid hormone profiles associated with a luteinized unruptured follicle. Although the midcycle 17β-estradiol surge was normal, the monkey with the luteinized unruptured follicle demonstrated (1) blunted midcycle bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone surges; (2) absence of disparity in the bioassayable luteinizing hormone:immunoassayable luteinizing hormone ratio during the gonadotropin surge; (3) absence of progesterone and 17α-hydroxyprogesterone secretion during the gonadotropin surge; and (4) delayed and blunted rise in progesterone and 17α-hydroxyprogesterone after the gonadotropin surge. These findings suggest that an impaired luteinizing hormone surge, perhaps mediated by insufficient midcycle progestin secretion, is one possible cause of the luteinized unruptured follicle syndrome. (Am J Obstet Gynecol 1986;154:839-47.)

Key words: Luteinized unruptured follicle, ovulatory stigma, impaired luteinizing hormone surge, midcycle progestin secretion

The concept that the oocyte might become entrapped in a luteinized unruptured follicle was proposed in 1966 to explain the discrepancy in ovulationn and conception rates in patients receiving clomiphene citrate.[1] The current terminology for this condition—the "luteinized unruptured follicle" syndrome—was initially used by Jewelewicz[2] to describe a condition in which "luteinized unruptured follicles secrete progesterone, causing all the progestational changes without actual ovulation." In these women, luteal phase plasma progesterone levels, basal body temperatures, and endometrial biopsy indicated that ovulation had occurred.

In 1978, Koninckx et al.[3] and Marik and Hulka[4] independently presented the first indirect evidence for the existence of the luteinized unruptured follicle syndrome. These authors reported that the luteinized unruptured follicle syndrome could be demonstrated by laparoscopic examination of the ovaries and failure to identify an ovulatory stigma in women during the luteal phase of apparently "ovulatory" cycles. Laparoscopic evidence of the luteinized unruptured follicle syndrome has been supported by failure to demonstrate increased peritoneal fluid volumes and concentrations of progesterone and 17β-estradiol that normally occur in women after follicular rupture and release of the steroid-rich follicular fluid into the peritoneal cavity.[5, 6] Indirect evidence for the luteinized unruptured follicle syndrome has also been suggested on the basis of serial pelvic ultrasound examinations.[7, 8] In these studies, criteria for a luteinized unruptured follicle included loss of a clearly demarcated follicle wall and presence of intrafollicular echoes in the absence of a rapid decrease in follicular size or appearance of free cul-de-sac fluid.

Laparoscopic and ultrasonic evidence for the luteinized unruptured follicle syndrome has not been confirmed by histologic study. Although ovarian biopsy of a putative luteinized unruptured follicle has demonstrated granulosa cell luteinization in women receiving clomiphene citrate, histologic identification of the entrapped ovum was not reported.[7, 9] To our knowledge, histologic demonstration of an oocyte entrapped in a luteinized unruptured follicle has been confirmed experimentally in the rat, rabbit, and monkey only after administration of indomethacin or prostaglandin F antiserum.[10]

Here, we report histologic and hormonal documentation of the luteinized unruptured follicle syndrome

occurring during a spontaneous menstrual cycle in a rhesus monkey. The unsuspected occurrence of this phenomenon during frequent peripheral blood assessment of midcycle hormone dynamics has proffered one possible cause of this heretofore poorly documented syndrome.

Material and methods

Sexually mature rhesus monkeys (*Macacca mulatta*, n = 6) weighing 4.1 to 6.5 kg and having at least two consecutive menstrual cycles of normal duration (25 to 30 days) were chosen for study. Housing, feeding, and general husbandry practices have been described previously.[11]

Blood was drawn daily beginning on day 8 of the menstrual cycle and the sera were assayed for 17β-estradiol by radioimmunoassay. When serum 17β-estradiol concentrations exceeded 100 pg/ml on two consecutive days, laparoscopy was performed with the animals under light ketamine anesthesia (Vetalar, Parke Davis, Morris Plains, New Jersey; 15 mg/kg intramuscularly) to document the presence of a putative dominant follicle. Monkeys were then fitted with a vest and mobile tether assembly, which permitted placement of a chronic indwelling femoral vein cannula and blood collection without anesthesia. Details of this procedure have been described previously.[11]

After the monkey had recovered from operation, 3.5 ml of blood was collected in sterile heparinized syringes every 2 hours. Plasma was harvested and frozen at −4° C; red blood cells were suspended in 0.9% saline solution and returned to the monkey. Laparoscopy was again performed, with the animals under ketamine anesthesia, 72 to 96 hours after the 17β-estradiol peak to document the presence of an ovulatory stigma. Blood sampling was discontinued on identification of the stigma. One monkey failed to demonstrate a stigma 96 hours after the 17β-estradiol peak. In this animal, laparotomy was performed and the ovary containing the putative dominant follicle was resected and fixed in Bouin's solution. The follicle was serially sectioned every 50 μm, stained with hematoxylin and eosin, and examined microscopically.

Plasma concentrations of luteinizing hormone, follicle-stimulating hormone, 17β-estradiol, progesterone, and 17α-hydroxyprogesterone were measured by radioimmunoassay.[13] Additionally, plasma luteinizing hormone was measured by the rat interstitial cell testosterone in vitro bioassay.[11] The bioassay dose-response curve was linear over the range from 2 to 50 μg. Bioassayable and immunoassayable luteinizing hormone were determined with human pituitary gonadotropin LER 1909-2 used as the standard.

The bioassayable luteinizing hormone surge initiation served as time zero for the temporal analysis of changes in circulating hormones. The bioassayable luteinizing hormone surge initiation and the surge initiation of immunoassayable luteinizing hormone and follicle-stimulating hormone were defined as the first plasma concentrations exceeding the means ± 2 SD of the preceding three values for each gonadotropin. The duration of rise for the gonadotropins was defined as the time interval between the surge initiation and the peak concentration of the respective gonadotropin. The surge duration was the interval from the surge initiation to the time when the postpeak concentration decreased to a value below that of the surge initiation.

Comparisons of time intervals were done with Friedman's nonparametric analysis of variance, since waiting times are often not normally distributed. Doubling times or half-times were computed for each time interval of interest, each hormone, and each monkey using 1n (2)/slope, where the slope was computed from a logarithmic linear regression. Since this ratio is not theoretically expected to be normally distributed, we analyzed the doubling or half-time with the use of Friedman's (to compare the hormones) and Wilcoxon's signed rank (to test if doubling times or half-times were significantly different from zero) nonparametric procedures. In monkeys with an ovulatory stigma, data were summarized by computing the mean and standard error for the five monkeys. The above parameters in

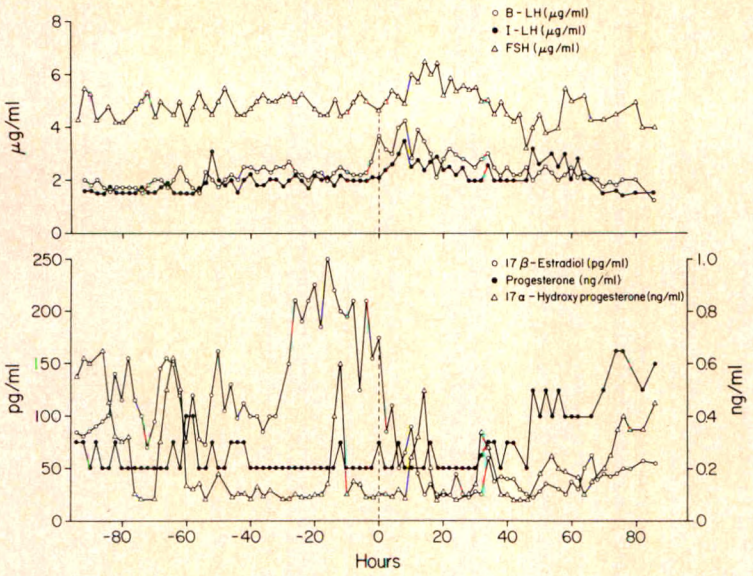

Fig. 2. Composite pattern of plasma gonadotropin *(upper panel)* and steroid *(lower panel)* concentrations measured every 2 hours during midcycle in the monkey with a luteinized unruptured follicle. Values are normalized to the onset of the bioassayable luteinizing hormone surge.

ovulatory monkeys and the monkey with the luteinized unruptured follicle were compared with the use of two-tailed *t* tests.

Results

Histologic examination of the resected ovary clearly demonstrated the presence of an oocyte entrapped in an early corpus luteum (Fig. 1). The oocyte measured 150 μm in diameter and contained an intact germinal vesicle and nucleolus. The cumulus mass was completed dissociated from the oocyte and detached cumulus or granulosa cells were present within the follicle among a fine fibrin network, occasional leukocytes, and erythrocytes.

The granulosa cells in the follicle wall were loosely radially arranged. Occasional areas gave the appearance of streaming into the central cavity. Capillary penetration into the granulosa cell layer was evident. The majority of granulosa cells were spindle-shaped with small nuclei, but some demonstrated an increased cytoplasmic volume and vacuolization. Luteinization of the theca cells was more advanced and a clear demarcation of theca and granulosa cells was present. Rare mitoses were present in both cell layers. Perifollicular stromal luteinization was also noted.

The temporal changes in plasma gonadotropin and steroid concentrations in the monkey with the luteinized unruptured follicle are presented in Fig. 2. The bioassayable luteinizing hormone surge initiation occurred 6 hours before the immunoassayable luteinizing hormone surge initiation and 10 hours before the follicle-stimulating hormone surge initiation. The duration of rise for bioassayable luteinizing hormone (8 hours) was similar to that for immunoassayable luteinizing hormone (6 hours) and follicle-stimulating hormone (8 hours). During this interval, the doubling times for bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone were 12.3, 12.2, and 14.1 hours, respectively. The surge durations for bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone were 20, 12, and 20 hours, respectively. Peak levels of 4.3, 3.5, and 6.5 μg/ml were achieved for bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone, respectively. No significant disparity in the ratio of bioassayable to immunoassayable luteinizing hormone was noted during the gonadotropin surge.

Serum 17β-estradiol concentration in this monkey demonstrated a progressive increase from the onset of blood collection to time zero + 16 hours with a doubling time of 36.6 hours. No significant increase in progesterone occurred before or during the gonadotropin surge; however, progesterone concentrations did gradually increase from time zero + 48 hours to time zero + 86 hours with a doubling time of 41.5 hours. Plasma 17α-hydroxyprogesterone concentrations demonstrated random increases throughout the sampling period but never exceeded 0.6 ng/ml. No sustained elevation in 17α-hydroxyprogesterone concentrations occurred until time zero + 64 hours, at which time 17α-hydroxyprogesterone concentration demonstrated a gradual increase with a doubling time of 17.5 hours.

The dynamic changes in plasma gonadotropins and

J Clin Endocrinol Metab 1985;60:886.)

Table I. Midcycle rise and surge durations of gonadotropins during ovulatory cycles

	Bioassayable luteinizing hormone	*Immunoassayable luteinizing hormone*	*Follicle-stimulating hormone*
Rise duration*	14.8 ± 1.6	9.2 ± 1.6	7.8 ± 1.7
Surge duration*	36.4 ± 4.8†	28.0 ± 2.4	32.8 ± 2.7

*Expressed in hours (mean ± SEM).

†$p < 0.03$ versus values in luteinized unruptured follicle cycle.

steroids in the five monkeys with an ovulatory stigma are presented in Figs. 3 and 4, respectively. In normally ovulatory monkeys, the immunoassayable luteinizing hormone and follicle-stimulating hormone surge initiations occurred 5.6 ± 1.2 hours (±SEM) and 7.0 ± 1.5 hours (±SEM), respectively, after the bioassayable luteinizing hormone surge initiation. During this interval, the mean doubling times (±SEM) for the bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone were 6.6 ± 1.3, 7.3 ± 1.2, and 8.0 ± 1.3, respectively. The midcycle rise and surge durations for gonadotropins are presented in Table I. Although the doubling times and temporal relationships among gonadotropins were similar in these monkeys and the one with a luteinized unruptured follicle, the surge duration of bioassayable luteinizing hormone and the secretion (area under the curve) of bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone in ovulatory monkeys were significantly greater than those observed in association with the luteinized unruptured follicle. In contrast to the monkey with the luteinized unruptured follicle, the bioassayable luteinizing hormone : immunoassayable luteinizing hormone ratio in monkeys with an ovulatory stigma demonstrated a significant increase from near unity before the bioassayable luteinizing hormone surge initiation to approximately 6 : 1 at the acme of gonadotropin secretion.

The doubling time of plasma 17β-estradiol, peak 17β-estradiol concentrations, and 17β-estradiol secretion (area under the curve) in ovulatory monkeys were similar to those observed in the monkey with the luteinized unruptured follicle. However, progesterone and 17α-hydroxyprogesterone concentrations increased >0.6 and 2.0 ng/ml, respectively, before or dur-

ing the bioassayable luteinizing hormone surge only in monkeys with an ovulatory stigma. This initial increase in progestins in ovulatory monkeys was followed by a plateau phase that lasted 24 to 48 hours; thereafter, sustained increases in progesterone and 17α-hydroxyprogesterone were initiated within 26 and 68 hours, respectively, of the bioassayable luteinizing hormone surge initiation. Before discontinuation of blood collections, progesterone and 17α-hydroxyprogesterone concentrations were in excess of 1.5 and 0.8 ng/ml, respectively, in all monkeys with an ovulatory stigma.

Comment

Numerous studies have recently drawn attention to the occurrence of the luteinized unruptured follicle syndrome in women with endometriosis or unexplained infertility and after induction of ovulation with clomiphene citrate.[3, 7, 12] In these studies, failure of ovum release was documented either by absence of an ovulatory stigma at laparoscopic visualization of the ovary or by failure to identify characteristic ultrasonic features of ovulation. Although ovum retention has been demonstrated in humans with ruptured follicles and in laboratory animals receiving antiprostaglandin treatments, our report constitutes the first histologic and hormonal documentation of the luteinized unruptured follicle syndrome during a spontaneous menstrual cycle.[10, 13]

Histologic examination of the putative luteinized unruptured follicle demonstrated characteristic features of an early corpus luteum without an ovulatory stigma. The observation of capillaries penetrating the granulosa cell layer is, according to the criteria of Corner,[14] consistent with a corpus luteum 2 days after ovulation. Clearly, demonstration of an entrapped oocyte with an intact germinal vesicle and nucleolus is evidence that "ovulation" did not occur.

Frequent blood sampling and assessment of midcycle hormonal changes in the monkey with the luteinized unruptured follicle and in monkeys with an ovulatory stigma revealed significant aberrations in the gonadotropin and steroid hormone profiles associated with the luteinized unruptured follicle syndrome. Although the midcycle 17β-estradiol surge and temporal relationship between gonadotropins were not abnormal, the monkey with the luteinized unruptured follicle did demonstrate several abnormalities, when compared with normal ovulatory monkeys, which included: (1) blunted midcycle bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormone surges; (2) absence of disparity in the bioassayable luteinizing hormone:immunoassayable luteinizing hormone ratio during the gonadotropin surge; (3) absence of progesterone or 17α-hydroxyprogesterone increases in conjunction with the gonadotropin surge; and (4) delayed and blunted rise in progesterone and 17α-hydroxyprogesterone after the gonadotropin surge. Although previous studies have suggested that midcycle hormonal patterns are normal in women with a luteinized unruptured follicle diagnosed by laparoscopy, our findings suggest significant abnormalities in midcycle gonadotropin and steroid dynamics in association with histologic confirmation of a luteinized unruptured follicle.

The necessity for a timely midcycle luteinizing hormone surge to trigger the complex process of ovulation is accepted. However, the precise quantitative and qualitative changes in midcycle luteinizing hormone secretion required to initiate ovulation remain unknown. The midcycle gonadotropin surge, particularly the bioassayable luteinizing hormone component, observed in association with a luteinized unruptured follicle was significantly blunted as compared with that in ovulatory monkeys. The cause of this impaired luteinizing hormone surge was not related to inadequate follicular 17β-estradiol secretion but was possibly due to insufficient progestin secretion. Recently, studies have demonstrated that progesterone will hasten the onset of the immunoassayable luteinizing hormone surge and that progesterone is required to establish the normal dimensions of an 17β-estradiol–induced gonadotropin surge.[15, 16] Since no obvious increase in progesterone or 17α-hydroxyprogesterone occurred either before or during the gonadotropin surge in the monkey with a luteinized unruptured follicle, insufficient progestin secretion may have mediated the blunted luteinizing hormone surge and subsequent unruptured follicle. The reason for insufficient progestin secretion at midcycle is unclear.

Midcycle progesterone secretion has also been implicated as a significant factor in fostering rupture of mature follicles. Although progesterone has been shown to induce ovulation in rat, rabbit, and hamster ovaries under various experimental conditions, there is no evidence to suggest that progesterone in the absence of gonadotropins can induce ovulation in vivo or in vitro.[17] Consequently, insufficient midcycle progesterone as a direct mediator of follicular rupture cannot be implicated as the sole cause of failure of oocyte release.

Others have postulated that the luteinized unruptured follicle syndrome is caused by transient psychological stress and attendant hyperprolactinemia that induce premature luteinization of the follicle in infertile women.[12] Another proposed mechanism suggests that follicular prostaglandin $F_{2\alpha}$ deficiency may result in failure of follicular rupture. Unfortunately, we cannot address these hypotheses because serum prolactin and follicular prostaglandin concentrations were not determined in our study.

Several distinct events make up the ovulation process, including ovum maturation and resumption of meiotic division, follicular luteinization and characteristic steroidogenic activity, and the complex process of follicular rupture and oocyte release. Although these events are likely controlled by independent mechanisms, the trigger for each event appears to be the luteinizing hormone surge. Our observation of impaired bioassayable luteinizing hormone and immunoassayable luteinizing hormone surges, possibly mediated by insufficient midcycle progestin secretion, in asssociation with an oocyte arrested in the first meiotic division and entrapped in a luteinized follicle, suggests that the luteinizing hormone trigger was sufficient to induce follicular luteinization, yet inadequate to permit resumption of meiotic division, follicular rupture, and release of a mature oocyte. These findings should be interpreted with caution since only one case of luteinized unruptured follicle has been unequivocally documented and because numerous other factors (for instance oocyte maturation inhibitor, nonsteroidal luteinization inhibitors and stimulators, nonsteroidal gonadotropin regulatory substances, prostaglandins, proteolytic enzymes, and cyclic adenosine monophosphate) may have a significant, yet unappreciated, role in the etiology of the luteinized unruptured follicle syndrome. Further, the abnormal midcycle hormonal patterns observed in this study may represent only one of several possible mechanisms of the luteinized unruptured follicle syndrome.

Discussion

Dr. Nathan Kase, New York, New York. Perhaps the most important concept in the understanding of ovarian physiology that has emerged during the past decade is the realization that the preovulatory ovarian follicle directly controls much of its physiologic fate, that is, achieving ovulation and corpus luteum function. By steroidal and nonsteroidal extragonadal messages the follicle directs and abets anterior pituitary gonadotrope cells to synthesize and release timely and appropriate concentrations of the gonadotropins follicle-stimulating hormone and luteinizing hormone. Similarly, the follicle exerts inhibitory dominance over maturation of other competing follicles in both the ipsolateral as well as the contralateral ovary by as yet uncharacterized suppressive hormonal messages. Finally, the endocrine microenvironment of the dominant preovulatory follicle induces and synchronizes the crucial events of ovulation—resumption of oocyte meiosis, the proteolytic disruption of follicle structural integrity leading to ovum extrusion, and the reorganization and vascularization of the granulosa cells preparatory to significant progesterone secretion.

Progesterone appears to play a signficant role in several of these midcycle events. Progesterone is influential in augmenting the gonadotropic reaction to gonadotropin-releasing hormone and secretion of both follicle-stimulating hormone and luteinizing hormone.

The possible role of intragonadal progesterone in synchronizing meiosis with ovum extrusion is intrigu-

ing. Although not established for mammalians, studies suggest two new biologic functions for progesterone: First, progesterone acts on the oocyte membrane to induce formation of a cytoplasmic protein messenger, which migrates to the oocyte nucleus and causes resumption of meiosis I. Second, progesterone, again operating via the oocyte membrane, appears to promote the appearance of another protein, which reduces or reverses the action of the granulosa cell oocyte meiosis inhibitor, which has arrested meiosis since the differentiation of the gonad in utero. In this way, during the luteinizing hormone surge, progesterone production in the microenvironment of the follicle causes resumption of meiosis at the same time that secretion of progesterone augments gonadotropin secretion. Extrapolation of this process to the human is premature. However, in vitro fertilization–embryo transfer studies such as those of Seibel et al. (Am J Obstet Gynecol 1982;142:568), correlated the luteinizing hormone surge with the progress of first meiotic division. This work demonstrated a relationship between the initiation of the luteinizing hormone surge with "germinal vesicle" condensation and the completion of meiosis I following the peak of luteinizing hormone concentrations.

In the paper "Histologic and hormonal documentation of the luteinized unruptured follicle syndrome," Schenken et al. have offered additional information on the importance of progesterone in the mechanics of ovulation in the rhesus monkey. This study provides histologic and hormonal documentation of a luteinized unruptured follicle occurring in a spontaneous menstrual cycle in the primate. By frequent blood sampling the midcycle hormonal dynamics in the animal with luteinized unruptured follicle are compared with similar measurements in five monkeys assumed to have ovulated normally. Significant midcycle observations include: normal estradiol; blunted concentrations of bioassayable luteinizing hormone, immunoassayable luteinizing hormone, and follicle-stimulating hormones; reduced bioassayable luteinizing hormone:immunoassayable luteinizing hormone ratios in the luteinized unruptured follicle syndrome; absence of progesterone and 17α-hydroxyprogesterone secretion during the gonadotropin surge, and a delayed as well as blunted rise in these steroids after the gonadotropin surge. The data suggest that an impaired bioassayable luteinizing hormone surge, possibly mediated by insufficient progestin secretion by the preovulatory follicle, might be a component in the etiology of the luteinized unruptured follicle syndrome. Although limited to its focus, this is extremely important work that demands confirmation and extension to other rhesus cycles and to the woman.

Certain limitations in the data must be noted and discussed before premature assumptions are made. Among the uncertainties that need clarification are the following:

1. Although these investigators are among the leaders in primate reproduction research, can they assure us that external visualization by laparoscopy is sufficient to document the presence of a dominant follicle in an ovary?

2. Are there data to validate the assumption that the presence of a stigma in the "normal" ovary is in fact proof of ovum extrusion?

3. Through their ingenious work with luteectomy these workers have shown the importance of the dominant follicle in the subsequent timing of the resumption of follicle maturation and next ovulation. We are not given information sufficient to show that oophorectomy in the animal with a luteinized unruptured follicle was associated with the expected delay of resumption of the next cycle. Hormonal data covering the remainder of the cycle in this animal are necessary to rule out the presence, albeit delayed, or an unnoted dominant follicle in the contralateral ovary but are not available in the manuscript.

4. Although sample frequency appears to be adequate (every 2 hours), it has recently been suggested that more frequent analyses might have displayed more detailed information with respect to the "appropriateness" of progesterone and gonadotropin secretions.

5. The investigators have shown the hormonal and structural details of a cycle in which an impaired dominant follicle remained unruptured and attenuated in what appeared to be a "normal cycle in a normal animal." To suggest that this offers documentation of a luteinized unruptured follicle syndrome is beyond the scope of the data. Was this animal infertile? Had there been previous cycle irregularities in the animal? In short, did this animal share the infertility of "undiagnosed etiology" we require in the human luteinized unruptured follicle syndrome?

6. The authors suggest that a midcycle hormonal abnormality was the proximal cause of the unruptured follicle in this animal. However, based on the histologic characteristics of the follicle represented in the authors' Fig. 1, there do not appear to be sufficient numbers of healthy granulosa cells to support the contention that this was an otherwise normal "unruptured preovulatory follicle." Are we seeing midcycle changes that are secondary to earlier menstrual or postmenstrual aberrations leading to failure of adequate preparation of granulosa cell maturation and function? Indeed, these workers have provided precisely this insight as the basis for the late consequences of early cycle application of nonsteroidal follicle maturation inhibitors.

7. We are asked to relate midcycle hormonal events to midcycle follicle histologic characteristics as seen only in the affected follicle. Would it have been useful to compare histologic characteristics of the affected follicle with those of follicles in normal "cases"?

8. Regarding the study design, the authors chose to preserve the affected follicle intact to show the entrapped ovum in a very convincing manner. They succeeded but at the expense of the lost opportunity to scrutinize the biochemical mechanisms at the intrafollicular antral level, thereby correlating circulating hormones with their microenvironment concentrations. Were the priorities inherent in the study design improperly "tilted" to display rather than interpret events?

In conclusion, and with the aforementioned quibbling put in proper perspective, this is an important insight into ovarian pathophysiology. The caution to restrain from extrapolating these interesting data to clinical reality is worth reemphasizing. However, without this kind of pathfinding, horizon-expanding work, typical of this investigative team, we would face the dismal frustrating prospect of wrestling with problems affecting the aspirations of our patients with directionless ignorance.

DR. E. STEWART TAYLOR, Denver, Colorado. I feel a little embarrassed to talk about something I know nothing about, but I found this a very interesting article, particularly for the physician who sees infertility patients in his office where everything appears to be normal but no pregnancy occurs. I think this does give thoughtful information about the inadequate luteal phase. It also sheds some light on why the empiric use of Clomid in a patient who appears to be normal is sometimes a successful event.

DR. M. **YUSOFF DAWOOD,** Chicago, Illinois. Could you tell us the length of the luteal phase of the monkey with the unruptured follicle?

DR. FRANK C. GREISS, JR., Winston-Salem, North Carolona. I am an ignorant, or maybe more so, as Dr. Taylor claimed to be, of this area. However, I wonder why more attention hasn't been focused on the early appearance of the estradiol surge and the fact that no immediate responses followed this. Could you explain this observation.?

DR. SCHENKEN (Closing). I greatly appreciate the pertinent commentary and probing questions. I agonized over many of these same questions when we were putting this manuscript together. I will try to address the questions in the order they were asked. First, is laparoscopic visualization of the ovary sufficient to identify the presence of a dominant follicle? We feel that laparoscopic visualization of the ovary is adequate when it is performed within 4 to 5 days of the time of ovulation. Before this time it is difficult to identify the dominant follicle. However, one can rely on measuring ovarian vein estrogen secretion to identify the ovary containing the dominant follicle.

Are there data to validate the assumption that the presence of a stigma is proof of ovum extrusion?

I am unaware of any studies that have looked at this question systematically. In women undergoing in vitro fertilization, oocytes have been aspirated from follicles bearing obvious stigmas. However, I think it is the experience of most in vitro fertilization programs that oocytes are rarely recovered from either follicles bearing a stigma or corpora hemorrhagica.

An appropriate pun here might be added: "A stigma will do to beat a dogma."

Dr. Kase also expressed concern that hormone data for the remainder of the cycle were not obtained and thus an unnoted dominant follicle in the contralateral ovary may have been present. Because of the rigorous blood sampling and multiple operations performed in this study, we felt that continued studying of this animal would place the monkey at unnecessary risk. The monkey with the unruptured follicle did have menses approximately 31 days after the oophorectomy. In view of previous data demonstrating that recruitment and ovulation of the dominant follicle require approximately 14 days, it is most likely that a new dominant follicle was recruited after the termination of our study.

In regard to the question on the monkey's menstrual cycle and fertility history, the monkey with the unruptured follicle conceived twice in a 2-year period before the study and had normal menstrual cycles for 8 months before our study. Consequently, I do not think this monkey had a diagnosis of unexplained infertility. Further, until we can ascertain whether the luteinized unruptured follicle syndrome occurs repetitively in each cycle, thus causing infertility, or whether the luteinized unruptured follicle is an isolated, infrequent event, I cannot agree with Dr. Kase's suggestion that infertility of unexplained etiology is a prerequisite for diagnosing the luteinized unruptured follicle syndrome.

The suggestion that an early follicular phase aberration led to a failure of normal mid cycle granulosa cell function, that is, progesterone secretion, is cearly possible. Indeed, the early follicular phase administration of porcine follicular fluid, which contains a nonsteroidal gonadotropin-inhibiting factor, will result in an inadequate luteal phase. We have also observed that monkeys with endometriosis and unruptured follicles commonly have a short luteal phase with inadequate progesterone secretion. Thus it is entirely possible that an early follicular phase abnormality may have been related to the genesis of this syndrome.

I completely agree with the recommendation that the histologic features of the unruptured follicle should have been compared with those of follicles demonstrating an ovulatory stigma. Unfortunately, as luck would have it, the monkey with the unruptured follicle was not identified until 4 days after all the other monkeys had completed the study. Consequently, to go back and resect the follicle would not have been temporally significant.

Dr. Kase also appropriately pointed out that our decision to histologically document the presence of an oocyte entrapped in a luteinized follicle was made at the expense of evaluating the "biochemical mechanisms" at the intrafollicular antral level. Accordingly, his question was, were the priorities in the study improperly tilted to display rather than interpret events? Clearly, our study was designed to document an event, but I do not think this was improper. In view of the fact that an oocyte entrapped in a luteinized unruptured follicle has never been documented histologically, it seems evident to me that a study designed to document unequivocally the existence of a syndrome should take precedence over a study designed to evaluate events associated with an undocumented syndnrome.

With regard to Dr. Greiss' question, the estrogen

surge in the monkey with the unruptured follicle did appear to occur earlier in relation to the bioassayable luteinizing hormone surge as compared with that in monkeys demonstrating an ovulatory stigma. However, with all the statistical machinations we used, we could not say that this was a significantly earlier occurrence of the estradiol surge.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

An analysis of the obstetric outcome of 125 consecutive pregnancies conceived in vitro and resulting in 100 deliveries

Mason C. Andrews, M.D., Suheil J. Muasher, M.D., Donald L. Levy, M.D., Howard W. Jones, Jr., M.D., Jairo E. Garcia, M.D., Zev Rosenwaks, M.D., Georgeanna S. Jones, M.D., and Anibal A. Acosta, M.D.

Norfolk, Virginia

One hundred twenty-five consecutive pregnancies conceived in vitro resulted in 100 deliveries of 115 babies. There were 23 clinical abortions (18.4%) and two tubal pregnancies. During the same interval 30 preclinical pregnancies occurred, but these pregnancies did not progress. There were 26 multiple pregnancies (37.1%) before the twelfth week; these reduced spontaneously to 14 (22.2%) multiple births at delivery. Eight infants were delivered prematurely, and three of these died. Three babies had some congenital abnormality. Vaginal bleeding occurred during pregnancy in 59% of patients. Cesarean section was the method of delivery in 56% of patients. Other complications of pregnancy were similar to those of comparable populations. (Am J Obstet Gynecol 1986;154:848-54.)

Key words: In vitro fertilization, pregnancy outcome, multiple pregnancy, infertility

More than 1500 deliveries of babies conceived in vitro have occurred throughout the world. There is yet no reported detailed analysis of the obstetric experience of all of a substantial number of pregnancies conceived in a single clinic. Steptoe[1] reported pregnancy outcomes in 242 deliveries.

Material and methods

Between April 15, 1981, and August 25, 1984, 125 clinical pregnancies were conceived in vitro at the Howard and Georgeanna Jones Institute for Reproductive Medicine. The methods of stimulation and monitoring of the patients under stimulation have been previously reported.[2-4] All but two received gonadotropins in supraphysiologic concentrations in an attempt to obtain multiple preovulatory oocytes for fertilization. Sixty-eight of these patients were stimulated with human menopausal gonadotropin (hMG). In 45 patients a combination of hMG and follicle-stimulating hormone (FSH) supplementation was used. In 12 patients FSH alone was used.

Of the 100 deliveries resulting, 12 were delivered at the Eastern Virginia Medical Center. Each of the other pregnancies, delivered throughout the United States and in three foreign countries, was evaluated through a questionnaire and personal communication with the patient and/or physician as indicated to obtain as complete information as possible. All babies in this series are being brought back for multidiscipline diagnostic evaluation for congenital abnormalities and for neurodevelopmental assessment in the Pediatric Department of the Eastern Virginia Medical School after 1 year of age or as soon thereafter as practical. Twenty-one babies have so far been evaluated in this manner.

During this same interval 30 additional patients achieved preclinical pregnancies. These are diagnosed (1) when the quantitative human chorionic gonadotropin (hCG) serum concentration rises to ≥10 mIU/ml on luteal days 11 to 13, (2) when a second hCG value is further elevated, (3) when these are accompanied by a second rise of serum estradiol and/or progesterone, (4) when the hCG level drops again to ≤5 mIU/ml or less before 14 days after the expected menstrual period, and (5) when menses is delayed no more than 14 days. No products of conception are encountered and no curettage is performed.

Table I. Outcome of 125 pregnancies conceived in vitro, April 15, 1981, to August 25, 1984*

Deliveries		100
Babies	115	
Clinical abortions < 20 wk		23
Tubal pregnancies		2
Total		125

*During this interval 30 preclinical pregnancies occurred but did not progress.

Results

The 125 pregnancies resulted in 100 deliveries, which produced 115 babies (Table I). There were 23

Total	56

clinical abortions before the twentieth week of gestation and two tubal pregnancies.

Abortions. The overall abortion rate in this series was 18.4%. Table II indicates the distribution according to method of stimulation. If preclinical pregnancies conceived during the same interval are considered as a proportion of all pregnancies, the rate of this occurrence is 19% (Table III). With this inclusion the total pregnancy loss is 33%.

Sex of babies. Sixty-four of the 115 babies were male. Fifty-one were female.

Method of delivery. Table IV indicates the method of delivery. In one case a premature breech infant was delivered by cesarean section after vaginal delivery of a premature stillborn infant. In another an abruptio placentae resulted during a manual attempt to rotate from breech to vertex after the vertex delivery of the first twin. The indications given for cesarean section are listed in Table V.

Prematurity. One pregnancy terminated at 25 weeks. An intramural myoma was present. Seven other pregnancies terminated before 36 weeks. Two of these were twin pregnancies, and one a triplet pregnancy. Two other patients among these seven had "T"-shaped uteri characteristic of intrauterine diethylstilbestrol exposure (Table VI).

Fetal losses. There were three deaths in infants delivered prematurely.

A 750 gm male was delivered of a 36-year-old mother at 25 weeks' gestation, 12 hours after spontaneous premature rupture of the membranes. After 5 weeks in neonatal intensive care and a septic course, small bowel resection for enterocolitis was carried out and death occurred while the infant was in septic shock at 6 weeks. No congenital abnormalities were found. The patient had an intramural uterine myoma, which was 1.5 cm

Table VI. Outcome of 100 deliveries of pregnancies conceived in vitro, April 15, 1981, to August 25, 1984

Length of gestation (wk)	*No. of pregnancies delivered*	*No. of living babies*
20-28	1*	0
28-36	7†	8
36-42	91	103
42	1	1
Total	100	112

*A 740 gm male infant died at 6 weeks.

†A 1360 gm stillborn first twin (second twin survived) and a 1300 gm stillborn infant at 29 weeks (intrauterine death).

Table VII. Multiple pregnancies* among 100 deliveries of pregnancies conceived in vitro, April 15, 1981, to August 25, 1984

	< 12 wk	*At delivery*
Twins	23	13
Triplets	3	1
Total	26(37.1%)	14(20.2%)

All multiple pregnancy deliveries occurred among the multiple transfers.

Another triple sac was reduced to a singleton and subsequently aborted. One single conceptus produced two sacs but was reduced to a singleton at delivery.

*Two or more conceptuses implanted (N = 69).

in diameter before pregnancy and enlarged considerably during pregnancy.

A 1620 gm male infant, the first twin, was stillborn at 29 weeks' gestation (mother age 34). Autopsy revealed no structural abnormalities. The second twin (1410 gm) was delivered by cesarean section and survived. There had been vaginal bleeding for the last 3 months of pregnancy. Five four-cell conceptuses and one two-cell conceptus had been implanted. There was marginal placenta previa.

A 1300 gm male stillborn infant was delivered at 29 weeks' gestation. Blood pressure had been elevated to levels of 200/110 mm Hg during the previous week. Weight gain had been 35 pounds. Prenatal visits were infrequent. Fetal movements had ceased and the fetal heart could no longer be detected 2 days before delivery. Autopsy revealed no congenital abnormalities.

Ectopic pregnancies. Ectopic pregnancy necessitating salpingectomy occurred in two patients.

Multiple pregnancies. There were 26 multiple pregnancies (26%) as determined by ultrasound before 12 weeks. Sixty-nine patients had had two or more conceptuses transferred. The average number of conceptuses transferred overall, including immature fertilized eggs, was 3.2. One was monozygotic, since only one conceptus had been implanted. Nine twin sacs were reduced to one sac. One triple sac was reduced to twins. Another triple sac was reduced to a single pregnancy at delivery. One was reduced to a single abortion. The resulting multiple delivery rate was 14% (Table VII). Ten of these 12 reductions before delivery were accompanied by vaginal bleeding. In addition, three of the 23 abortions were recognized to be twin pregnancies. One of these twin sacs that aborted occurred in another pregnancy in the same patient, who previously had reduction of twin sacs to a single pregnancy and who again had only a single conceptus transferred.

Table VIII. Vaginal bleeding during 91 of 100 pregnancies conceived in vitro, April 15, 1981, to August 25, 1984

Trimester bleeding began	*n*
First	49
Second	3
Third	2
Total bleeding	54 (59%)
No bleeding	37

Table IX. Location of placenta by ultrasound in 71 of 100 pregnancies, April 15, 1981, to August 25, 1984

Location	*n*	*%*
Anterior	31	43
Posterior	19	27
Fundal	18	26
Complete placenta previa	1	1
Low-lying placenta	2	3

Vaginal bleeding. Fifty-nine percent of the 91 patients from whom an adequate history was obtained had vaginal bleeding during pregnancy. One had a placenta previa and another marginal placenta previa (Table VIII). Vaginal bleeding was as common among patients with single transfers as among those with multiple transfers. Bleeding frequently occurred during a period of days or weeks. One patient who was delivered at term was advised to have a curettage performed in the third month because of the quantity of persistent bleeding.

Placental location. The location of the placentas in the 71 patients from whom this information could be recovered is listed in Table IX.

Congenital abnormalities. Congenital abnormalities occurred in three infants.

A 3530 gm male infant born to a 41-year-old mother with no family history of neural tube defect had a 6 to 7 cm myelomeningocele of the lumbar spine. At the age of 6 months a nonemergency ventricular shunt was carried out because of evidence of incomplete drainage.

Table X. Amniocentesis among 100 pregnancies conceived in vitro, April 15, 1981, to August 25, 1984

Patients ≥ age 35	39
Amniocentesis	27
No amniocentesis	12
Anterior placenta (age 39)	1
Aged 35 and 36	2
Elected no amniocentesis	4
Reason unknown	5

Table XI. Pregnancy-induced hypertension among 86 of 100 pregnancies conceived in vitro, April 15, 1981, to August 25, 1984

Severe PIH at 29 wk, delivered by CS	1
Severe PIH at 29 wk, fetal death in utero	1
Moderate PIH, magnesium sulfate given	3
Mild PIH	5
Total	10(12%)

PIH = Pregnancy-induced hypertension; CS = cesarean section.

Development appears normal. There is a significant neurological deficit in the lower extremities.

A 3960 gm male infant, delivered of a 32-year-old para 0 woman, was found soon after birth to have a small congenital membranous ventricular septal defect. This did not cause any symptoms or require treatment. When this child returned at 1 year of age and was subjected to the intensive evaluation, ultrasonography detected a stricture at the ureteropelvic junction. This was successfully repaired.

A 3500 gm male infant, born to a 37-year-old para 0 woman, was found at birth to have absence of much of the external ear on the right side (microtia). Hearing is normal.

No other abnormalities have been found among the 115 babies delivered, including 21 intensively evaluated babies.

Amniocentesis. Amniocentesis was performed in 27 of 39 patients whose age was ≥35 years. All chromosome analyses were normal (Table X).

Abortuses. Nine abortuses were analyzed for chromosome content. Seven were normal. Two showed mosaicism as follows: (1) 46,XX/47,XX,15+; (2) 46,XX/46,XX,15−,t(15,21)(p11,q11).

Other complications of pregnancy. Ten of the 86 patients from whom a specific history could be obtained concerning pregnancy-induced hypertension had experienced this complication. One fetal death was associated with severe pregnancy-induced hypertension at 29 weeks (Table XI). Apgar scores are displayed in Table XII.

Weights of babies. The weights of 85 singleton babies are plotted in Fig. 1. With use of the tables designed

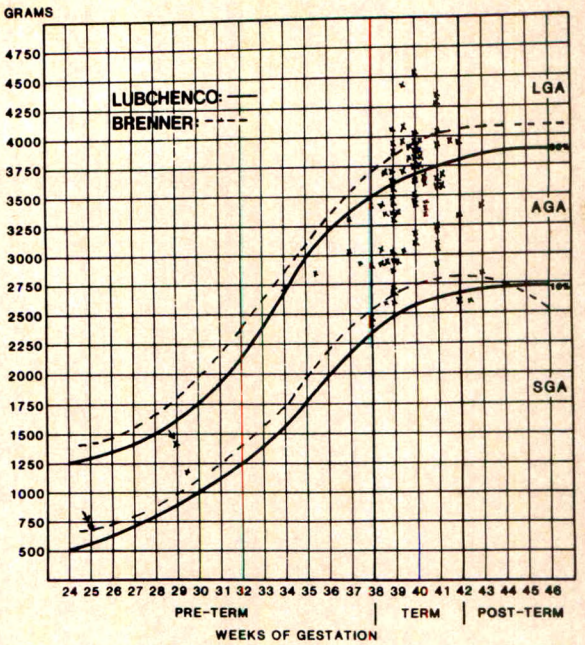

Fig. 1. Fetal growth profile with weights of 85 singleton babies. Appropriate for gestational age *(AGA)*, 65 (77%); small for gestational age *(SGA)*, 6 (7%); large for gestational age *(LGA)*, 14 (16%).

Table XII. Apgar scores among 81 babies conceived in vitro, April 15, 1981, to August 25, 1984

	No. of babies
Stillborn	2
Apgar scores <7 at 1 min	5
Apgar scores <7 at 5 min	0

by Brenner et al.,[6] 14 (16%) qualified as large for gestational age. Six (7%) were small for gestational age.

Comment

In general, the obstetric results in these 100 patients were consonant with expectations when their age and other special characteristics are considered.

No complications uniquely consequent to this method of conception can be identified beyond the 59% incidence of vaginal bleeding and the higher multiple pregnancy rate.

The higher incidence of induced multiple pregnancies inherent in multiple-conceptus transfer predisposes to a higher incidence of prematurity and fetal loss, as well as abnormality. One fetal loss, on the basis of incomplete information, appears to have been a preventable obstetric accident.

The incidence of prematurity, which was responsible for another fetal loss, appears comparable to that of general experience when multiple pregnancy and intrauterine abnormalities are considered.

The examination of all of these babies for congenital abnormalities has been intense and is probably accurate. The three babies having major abnormalities among the 115 babies described here are consistent with results in studies of larger groups reporting incidences from 2.1%[7] to 3.3%,[8] but final conclusions must await larger numbers. The increased proportion of multiple pregnancies will predispose to a higher proportion of major abnormalities among babies conceived in vitro. The intensive multidiscipline evaluation that is being conducted in all infants conceived in vitro in this program will yield more thorough information, but controls may be difficult to locate. Compliance has been near 100%.

The very high cesarean section rate (56%) probably reflects some concern for the "premium" nature of these pregnancies in addition to the increased numbers of multiple pregnancy, older maternal ages, and increased pregnancy-induced hypertension. It is identical with that reported by Steptoe.[1]

The incidence of pregnancy-induced hypertension in this group probably reflects the older ages, the primigravidity, and the nature of this disease. Evidence of casual obstetric care of some of these pregnancies that were conceived with such difficulty suggests a need to reinforce advice to seek quality care.

The inherent inefficiency of human reproduction and particularly the embryonic loss between fertilization and clinical pregnancy has been explored by Leridon,[5] Edmonds et al.,[9] and Miller et al.[10] Edmonds et al. found that 198 exposures in ovulatory normal volunteers produced 118 (59.6%) chemically detectable pregnancies, but there were only 51 (25.6%) clinically detectable pregnancies and 45 (22.5%) term pregnancies.

The proportion of preclinical pregnancies in this in vitro fertilization series is of somewhat less magnitude and represents, in part, less sensitive detection. The clinical abortion rate of 18.4% among the pregnancies here reported is comparable to that occurring naturally under similar scrutiny. Steptoe[1] reported a clinical abortion rate of 32% among 726 conceptus transfers.

The overall rate of achieving a live birth from transfer of one or more conceptuses in the Norfolk program in the year preceding April, 1985, is 18%, or 4% less than the normal experience of Edmonds et al. During that year the pregnancy rate among 136 cycles in consecutive new patients having the preferred protocol stimulation (hCG/hMG) was 32.3% of all conceptuses transferred.

Improvement year by year has been slow but steady. With increasing knowledge concerning stimulation techniques to produce more consistently two or more fertilizable ova of good quality and with better patient selection techniques, it is quite reasonable to expect that the natural experience may be significantly exceeded.

Discussion

Dr. Charles R. Brinkman III, Los Angeles, California. This is a very interesting report on the outcome of 127 women who achieved clinical pregnancies after in vitro fertilization. As a perinatologist, I will focus my comments on some of the perinatal and demographic aspects of this paper.

Of the women who carried their pregnancies beyond 20 weeks, 39% were older than 34 years of age. While this percentage is quite high, undoubtedly because of the infertility history, it is interesting to look at the trends occurring regarding maternal age and childbirth. In California, between 1978 and 1982, there was a 1.4% increase in births to women over the age of 34, from 5.2% of 357,000 births to 6.6% of 432,000 births.[1] During the same period, there was a 1.5% increase in Los Angeles County. For comparison, I selected two hospitals that serve communities inhabited by a high proportion of career-oriented professionals. In these communities, the percentage of births to women over 34 has increased from 10% to 15.4% in the same 5-year period. This particular group of pregnant women is usually considered to be at increased risk for many of the medical complications encountered during pregnancy and may account for the 12% rate of pregnancy-induced hypertension observed in this report.

The second facet I wish to discuss is that of a 54% primary cesarean section rate; of the women undergoing primary cesarean birth, apparently half had a trial of labor while half apparently did not, resulting

in an elective primary cesarean section rate of 25%. During 1981, for comparison, in California and Los Angeles County, the primary cesarean birth rate was 10.9% and in the two selected hospitals previously mentioned, it was 17.9%. In addition, Cohen et al.[2] recently reported a primary cesarean rate of 13% in 60 infertility patients managed by maternal-fetal medicine subspecialists. While there is no queston that these are "premium" pregnancies, I believe we would all agree that every pregnancy should receive the level of care necessary to maximize successful outcome for mother and infant. I am not sure that this liberal use of cesarean birth is necessary to meet that aim.

The last point I wish to make has to do with the perinatal mortality rate of this small series. The fetal death rate is 17.4 per 1000, which is almost three times the rate in California for 1981. There were no neonatal deaths, as one infant survived 6 weeks and should be classified as an infant death. Therefore, the perinatal mortality rate is 17.4 per 1000, which is appreciably higher than the 12.5 per 1000 reported for California in 1981.

My questions for Dr. Andrews are: (1) What screening and counseling were carried out before in vitro fertilization on these patients in order to assess perinatal risks? (2) What recommendations were made to the attending physicians regarding antepartum risk assessment, such as α-fetoprotein assessment, diabetic screening, and general pregnancy management? (3) Are there any special precautions or procedures that can be done during the in vitro fertilization procedure to reduce the well-recognized increased risk of the woman who is older than age 34 for chromosomal anomalies?

2. Cohen AW, Menuti MT, Gabbe SG, Leston RM. High-risk obstetrics. The three-year experience of four subspecialists. J Reprod Med 1985;30:472-7.

Dr. Richard H. Paul, Los Angeles, California. I was also interested in the management approach that these unique pregnancies might require. I think you indicated that some pregnancies did reach or exceed 40 weeks and one was delivered at 42 weeks. What test or what surveillance approach would give you reassurance that everything is well in permitting a wait-and-see attitude in this very unique patient?

Dr. John T. Queenan, Washington, D. C. I was very fascinated by the 16% incidence of large for gestational age babies in your report. Additionally two of the three stillborn infants at 29 weeks were appreciably larger than we would have expected for a 29-week gestation.

Was there any explanation for the large for gestational age babies or the rapid growth in utero? Were all of these patients screened with glucose tolerance tests?

Dr. Frederick P. Zuspan, Columbus, Ohio. The rate of pregnancy-induced hypertension or hypertension in pregnancy is about 50% higher than we would anticipate nationally.

I would ask you, in the socio-economic group that this would represent, what would be the rate of pregnancy hypertension since there were probably more who had underlying chronic hypertension? Is there any way to ascertain this? It may be that this is just a spurious finding in the first hundred.

Dr. Luther M. Talbert, Chapel Hill, North Carolina. I would just like to say that we have seen the same kind of phenomena of very high cesarean section rates in the considerably smaller numbers of in vitro fertilization patients that we have delivered, mostly not in Chapel Hill. I think most of the cesarean sections we have seen have been engendered by the tremendous level of anxiety that gynecologists caring for these patients have had just because of the precious nature of the pregnancies.

I wonder if Dr. Andrews has any suggestions as to what we should say to the patient's own obstetrician when we refer her back to the community. Should we somehow discourage the performance of cesarean section in more than half of these patients?

Dr. Paul G. McDonough, Augusta, Georgia. I would like to ask Dr. Andrews about the cytogenetic findings in the studied clinical abortions. He indicated that two of the cases that they studied were "mosaics." Mosaicism may suggest a postsegmentation error during early embryogenesis. It is important, when possible, to characterize the nature and source of the cytogenetic abnormalities that occur with human in vitro fertilization. It is conceivable that these abnormalities may be quite different than those occurring in human in vivo fertilization. This type of information will help us to understand whether female meiosis II errors are more frequent than mitotic errors in early embryogenesis.

Dr. Andrews also mentioned one set of monozygotic twins in their in vitro fertilization program. The incidence of monozygotic twinning in in vitro fertilization should be monitored closely. I know of one other instance of well-documented monozygotic twinning after single-embyro transfer. An increased incidence of monozygotic twinning compared to that in vivo might suggest that technical factors in human in vitro fertilization may predispose to early blastomere separation.

Dr. Muasher (Closing). The observation by Dr. Brinkman that the pregnancy rate in women in California over the age of 34 is increasing sounded very interesting to me. Actually, when we consider patients with tubal disease who come to us for in vitro fertilization who are above the age of 40, we find no difference in the pregnancy rate after in vitro fertilization from that in patients who are under the age of 40 in our program. Furthermore, the pregnancy rate in the age group 35 to 39 is higher than the pregnancy rate in the age group less than 35.

Of course, the numbers are not statistically significant, but the observation itself I find interesting.

There were many different questions about the cesarean section rate. I think I agree with everyone that this is undoubtedly a very high cesarean rate (primary cesarean section rate), but I think it is also very understandable in view of the long history of infertility of these patients. I would also like everyone to know that many of these patients have tried in vitro fertilization with us and with other programs multiple times.

Much expense has been necessary to achieve a success, and neither they nor their obstetricians want to have any obstetric catastrophe during labor.

A very important illustration, I think, is one of the patients who had a twin pregnancy and had a vaginal delivery of the first one and a cesarean section for delivery of the other. This patient was managed by a board-certified person in maternal-fetal medicine, and after delivery of the first twin, there was an attempt to do an external podalic version to deliver the second one, as that twin was presenting as a breech.

During that attempt the fetal heart rate dropped, and there was significant vaginal bleeding. Fortunately an emergency cesarean section was performed and the baby did well, but I don't think anybody would argue that if the second baby had died, it would have been much better to perform a cesarean section in this particular case from the beginning.

As far as the high rate of perinatal mortality, I think the numbers that we presented are only for 115 babies, and I think the numbers are small to comment on that.

We usually take a very careful history from all our in vitro fertilization patients. Regarding the question about any of these patients having chronic hypertension, as far as I know, none of them did. Of the 10 patients with pregnancy-induced hypertension, seven or eight were just mild cases of pregnancy-induced hypertension. Only two cases, one ending in a stillbirth at 29 weeks and one ending in a cesarean section and delivery at 39 weeks, were severe pregnancy-induced hypertension.

We tried to suggest to the patients that they should have contemporary obstetric care, and we are in constant contact with them by telephone. However, many of these patients, as Dr. Andrews said, were delivered throughout the United States and in three foreign countries, and it is very difficult to contact their obstetricians and give them suggestions regarding what they should do during labor.

As far as the chromosomal abnormalities suggested by Dr. McDonough, we have had the opportunity to examine nine cases of abortus material, and in two of them there was an abnormality. One of the abnormalities was a true mosaic involving a trisomy 15 in one of the cell lines: 46,XX/47,XX,15+. In the other case, there was also a mosaic pattern, and in this case there was a 15-21 translocation: 46,XX/46,XX,15−,t(15,21)(p11,q11)

I am aware of some reports from Edwards and Steptoe's group in England, for example, of two cases of abortus material that had triploidy and there was one case of abortus material that had autosomal monosomy. We have not seen these in our group.

Focal vulvitis: A characteristic syndrome and cause of dyspareunia

Features, natural history, and management

Ben M. Peckham, M.D., Ph.D., Dennis G. Maki, M.D., Jeffrey J. Patterson, D.O., and Gholam-Reza Hafez, M.D.

Madison, Wisconsin

Based on the study of 67 affected women during a period of 15 years, we report the clinical features and natural history of focal vulvitis, a unique syndrome characterized by severe and persistent superficial dyspareunia and the presence of one to 11 (median three) minute, exquisitely tender areas of focal inflammation or ulceration on the mucosa of the vestibule. Three fourths of all lesions occur around the Bartholin gland ducts or between them posteriorly. Histopathologic study of tissues from seven patients has not shown a characteristic pattern of inflammation and fails to confirm a reported association between these lesions and the minor vestibular glands. These histologic studies and an in-depth clinical and epidemiologic investigation in nine patients, including microbiologic studies to identify infection by herpes simplex virus, *Neisseria gonorrhoeae, Staphylococcus aureus,* β-hemolytic streptococci, *Chlamydia trachomatis,* mycoplasmas, *Candida* sp., trichomonads, or *Mycobacterium* sp., have not established an infectious etiology for this syndrome or evidence that it represents an unusual form of an autoimmune disease or Behcet's syndrome. Treatment with topical antimicrobial or corticosteroid creams, antibiotics given systemically, or cryotherapy has not been of demonstrable benefit. Approximately one half of patients eventually experience spontaneous remission but many appear to remain symptomatic indefinitely. Surgical excision of the hymenal ring and contiguous mucosa of the vestibule has brought relief and permitted resumption of sexual activity in seven of eight treated patients. While promising, operation should be reserved for patients who have experienced unremitting dyspareunia associated with the characteristic focal inflammatory lesions for at least 6 months. (Am J Obstet Gynecol 1986;154:855-64.)

Key words: Focal vulvitis, dyspareunia, Bartholin's gland

The complaint of persistent vulvovaginal burning or discomfort, often associated with dyspareunia or pain on the insertion of tampons, usually suggests vulvovaginitis. In most patients, gross inspection and microscopic examination of vaginal discharge allows specific diagnosis and the institution of effective therapy. However, when the cause of persistent superficial dyspareunia is not obvious after thorough evaluation, particularly when there has been a history of many treatment failures, the possibility of a more rare condition, focal vulvitis, should be considered. Woodruff, Parmley, and Friedrich[1-3] have recently provided a clear description of this syndrome and attribute it to inflammation of minor vestibular glands of endodermal origin found in the vestibule. Woodruff (personal communication) has further uncovered two descriptions of this syndrome in the old literature dating from 1880[4] and 1928,[5] which indicate that it is not new. Pelisse and Hewitt,[6] in 1976, reported on 30 patients with "erythematous vulvitis in plaques" and described submucosal infiltration by chronic inflammatory cells. Others have reported similar lesions producing superficial dyspareunia.[7-9] In 1971, Dr. William Keetel described this syndrome to one of his students as "focal vulvitis" (Heuss C, personal communication), the name that we independently selected years before learning of Keetel's observations.

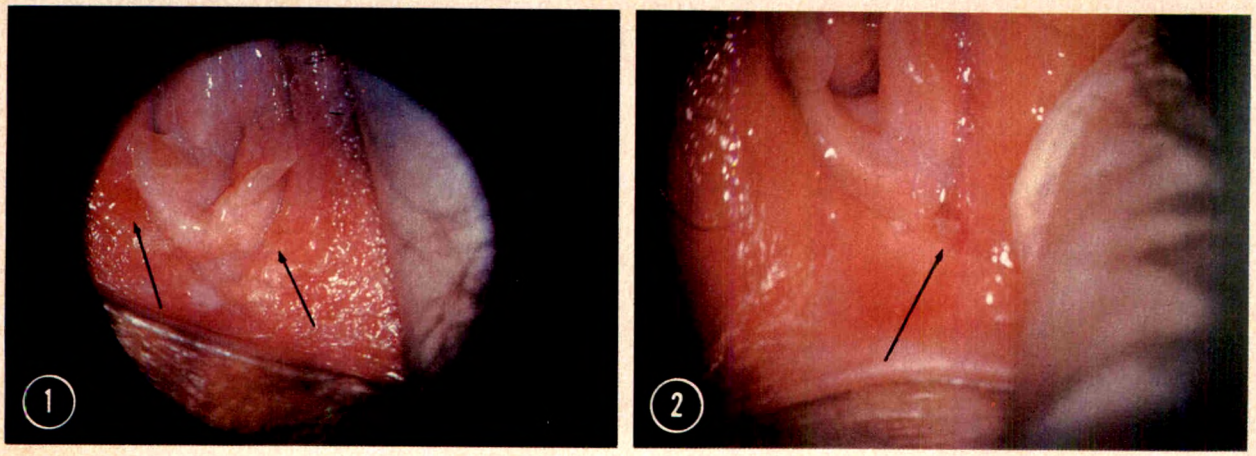

Fig. 1. The focal erythematous lesions of focal vulvitis *(arrows)* may be very inconspicuous or stand out clearly on comparison with the surrounding normal mucosa, depending on the intensity of inflammation and the character of the incident light used during examination.

Fig. 2. Focal vulvitis presenting as a minute ulcer *(arrow)*.

Until the recent reports by Woodruff et al.,[1-3] this entity had not been recognized as a distinct syndrome in the modern medical literature, and little published information has been available on its natural history or possible causes. We report clinical features, studies undertaken to identify its cause, the results of various forms of empiric therapy, and the natural history of focal vulvitis, based on the initial evaluation and longitudinal follow-up of 67 patients fulfilling criteria we propose for the syndrome, who were seen between 1971 and 1985.

Methods and results

Sources of data. One of us (B. M. P.) became aware of the syndrome in 1971, after seeing two patients whose sexual relationships had been severely impaired by excruciating superficial dyspareunia. Both had minute, focal, exquisitely sensitive inflammatory lesions on the vulvovestibular mucosa at the hymenal ring, which we have found to be highly characteristic of this condition. After repeated examinations failed to reveal evidence of vaginitis and after empiric treatment with steroidal creams and interdiction of intercourse proved ineffectual, excisional biopsy was performed to obtain tissue for histopathologic and viral studies. Cultures failed to reveal evidence of a viral cause. On microscopic examination, cells characteristic of chronic inflammation were seen in the submucosal tissues. Oral prednisone given on the possibility that the condition might represent an aberrant form of pemphigoid was also without therapeutic effect.

In 1980, two of us (B. M. P. and J. J. P.) realized that we had independently recognized this condition as a unique clinical entity and that we were both encountering increasing numbers of affected patients. It was agreed that a more formal, prospective clinical, epidemiologic, and microbiologic study should be undertaken.

All 67 patients described in this report have been examined by one or more of the authors in the University of Wisconsin Hospital Clinics (B. M. P. and D. G. M.) or in one of the School's Family Medicine Clinics (J. J. P.). Nearly all were referred for evaluation because of persistent pain and unexplained dyspareunia and others, for what was believed to represent intractable vaginitis. Nine patients have been studied in depth to an attempt to identify possible medical conditions, sexual practices, or microbial pathogens associated with this syndrome, possibly causally.

Case definition for the syndrome. Criteria included vulvar pain, dyspareunia, or pain with insertion of tampons, associated with: (1) one or more minute, exquisitely sensitive, focal inflammatory lesions located in the vestibule and (2) no identifiable cause such as herpes progenitalis, bacterial or *Candida* vaginitis, or pemphigoid.

Characteristic lesions. Casual examination of the vulva with the naked eye under room light rarely allows detection of the characteristic focal inflammatory lesions unless the examiner carefully everts the hymenal ring and exposes the inner surfaces of the labia minora. Lesions are most easily seen with a colposcope but can almost always also be seen with the naked eye with adequate exposure and a bright light source. When the hymenal ring is rolled toward the vaginal orifice with a moistened applicator, the deep crypts that lie just lateral to the ring and the urethral meatus are easily exposed and one or more exquisitely sensitive 3 to 10 mm areas of focal erythema, in most cases without swelling or ulceration, are visible (Fig. 1). Touching individual lesions with the tip of a cotton applicator (the "touch test") is essential diagnostically: The lesions

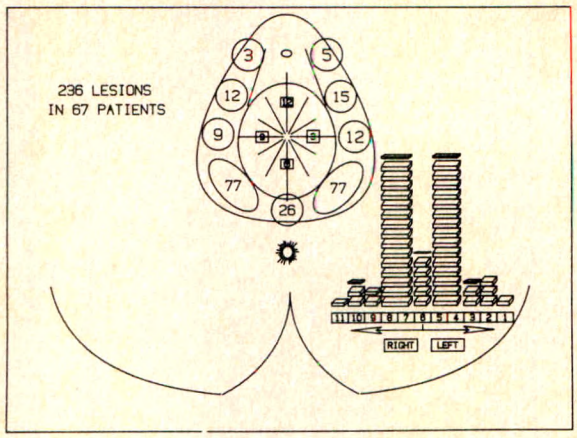

Fig. 3. The vulvar distribution of 236 lesions of focal vulvitis seen in all 67 patients after 4 and 5 o'clock and 6 and 7 o'clock positions have been combined. Each complete block represents five lesions. *Numbers inside circles* represent total number of lesions encountered at that location.

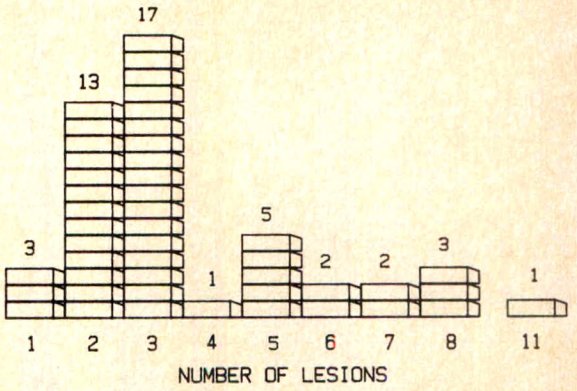

Fig. 4. The number of painful lesions per patient recorded in 47 patients with focal vulvitis evaluated by a single observer (B. M. P.).

are invariably found to be exquisitely sensitive to touch; moreover, the tenderness is characteristically very focal and can be reproduced with remarkable precision by independent observers. The contiguous mucosal surface, only millimeters from a lesion in all directions, is completely normal in appearance and nontender to touch with the applicator.

Fifteen of our 67 patients (22%) showed minute discrete ulcers in the mucosa at one or more of the sites of inflammation and focal tenderness (Fig. 2). In some patients, the mucosa was superficially denuded or appeared split. In others, tiny indolent ulcers could be seen deep within the crypts, out of sight unless the area was fully exposed (Fig. 2).

Location of lesions. Lesions in each patient were mapped diagramatically (Fig. 3). Lesions were most commonly located in the area about or posteriorly between the Bartholin duct openings between 4 and 8 o'clock. (The duct orifices, however, are usually not visible to the naked eye and even through the colposcope can be identified only occasionally.) In this location, inflammatory lesions were usually largest, often measuring from 8 to 10 mm in diameter. Evidence of associated inflammation or especially suppurative infection of the Bartholin glands, however, has not been seen. When lesions occur at 6 o'clock as well, the mucosa of the vestibule between 4 and 8 o'clock may be diffusely erythematous. There is seldom a well-formed crypt in the 6 o'clock position and, when it is involved, redness is more diffuse and may even extend onto the surface of the perineal body.

When lesions at 4 and 5 o'clock and at 7 and 8 o'clock are combined (Fig. 3), these locations account for 65% of all lesions; when the lesions at 6 o'clock are added, 76% of all lesions occur posteriorly, between the 4 and 8 o'clock positions. In 54 patients (81% of the total group), all of the lesions identified were located on the mucosa of the vestibule between 3 and 9 o'clock inclusive.

Number of lesions. Among 47 patients seen by B. M. P., the number of sites per patient varied from one to 11 (median three). Patients with either two lesions (13 patients) or three lesions (17 patients) accounted for 64% of the affected patients (Fig. 4).

Initial clinical presentation and features of patients. The features of these patients and the vulvitis are summarized in Table I. All were Caucasian. The age at the onset of the syndrome varied from 14 to 67 (median 25) years (Fig. 5); 49% had the onset in their 20s. Fifty-one percent had been pregnant; approximately one fourth had had a spontaneous or induced abortion.

The records of 50 patients provide reasonably detailed information concerning the character of the syndrome's onset. In 39 patients (80%), the onset was described as sudden and first noted during a specific intercourse. Eleven patients (20%) reported a more gradual onset, occurring over a period of weeks or months. In 18 (36%) of these 50 patients, their physicians had ascribed their symptoms to vaginitis, most often *Candida* vaginitis. However, even when there was microscopic evidence of vaginitis during our initial examination, successful treatment of the vaginitis did not result in resolution of the lesions or relief of symptoms.

In six patients, the characteristic pain was experienced with the first attempt at intercourse; one of these patients had been experiencing pain with the insertion of tampons for several years previously. With the exception of these six patients, all of the patients had enjoyed pain-free intercourse with one or more partners for months or years prior to the onset of focal vulvitis. Once vulvitis occurred, however, most of these women markedly curtailed the frequency of sexual intercourse and many had become essentially abstinent.

Four other patients indicated that they had first experienced pain when inserting tampons, and two be-

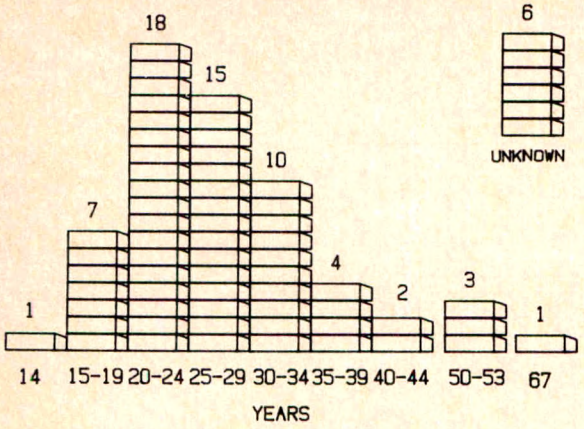

Fig. 5. Age distribution of 67 patients at the onset of symptomatic focal vulvitis.

lieved that the tampon inserter was responsible for their symptoms.

Although many of these patients had had urinary tract infections in the past, urinary tract symptoms or evidence of active infection has not been associated with this syndrome. Recurrent symptomatic cystitis or urethritis was reported by only two of these patients.

A number of the women, after repeated negative examinations, had been referred for psychiatric counseling but had continued to experience incapacitating dyspareunia.

The length of time symptoms had been present at the time of our initial evaluation varied from a few months to 26 years (Table I). Nearly half the patients had been symptomatic for ≥2 years.

In-depth study of nine patients. In 1981, when it seemed clear that many patients presenting with dyspareunia had focal lesions producing a characteristic syndrome, nine patients fitting the case definition were prospectively evaluated in the University Hospital Clinics for factors associated with the syndrome, in an effort to seek a cause. This evaulation consisted of a detailed sexual history (Table II), a comprehensive medical evaluation, pelvic examination with colposcopic photography, laboratory studies (hemogram, erythrocyte sedimentation rate, 12-test biochemical profile, tests for rheumatoid factor and antinuclear antibodies, IgG, IgA, IgM, and IgE levels, and urinalysis), microscopic studies for evidence of *Candida, Trichomonas,* and nonspecific vaginitis, and vaginal cultures to detect colonization by β-hemolytic streptococci, *Staphylococcus aureus, Neisseria gonorrhoeae, Chlamydia trachomatis, Mycoplasma* sp., herpes simplex virus, and *Mycobacterium* sp.[10]

No intercurrent conditions, allergies, family history of gynecologic diseases, or extragenital physical findings emerged in a frequency that could be considered significant, and none of the nine women reported knowledge of a first- or second-order relative with similar symptoms. Moreover, except for mild anemia in one patient and subnormal levels of IgA in another, the screening laboratory studies, including absolute granulocyte and lymphocyte counts, sedimentation rate, and immunoglobulin levels, were uniformly in a normal range in all nine patients. None of the patients showed any clinical or laboratory evidence of constitutional illness or an autoimmune disorder.

*The relative frequencies of various factors are based on different numbers of patients for each factor for which complete data are available.

The results of the detailed sexual history and other relevant historical information are shown in Table II. The menstrual history was unremarkable in all nine patients, and no single form of birth control predominated. Four of the women had used a vaginal douche but none had used commercial vulvar sprays or perfumes before onset of the syndrome.

The age at first intercourse ranged from 19 to 27 years and the group had been sexually active for an average of 7 years before becoming symptomatic; two women, however, had experienced characteristic symptoms with first intercourse and had continued thereafter to suffer from dyspareunia. Half of the group had had five or more sexual partners, and six (60%) had acquired a new partner in the 6 months before onset. Nearly all had engaged in cunnilingus and fellatio, but only one had engaged in anal intercourse. Eight of the nine women had masturbated at variable frequency before the onset of vulvitis. None had had any homosexual experience.

Most notably, the frequency of intercourse fell precipitately with the onset of vulvitis, from a median of four times per week before onset of symptoms to far less than once per week after they began to experience dyspareunia; five women had become abstinent.

Few had had a sexually transmissible disease before becoming symptomatic and, although two thirds had been treated for one or several bouts of symptomatic urinary tract infection, none experienced dysuria or other irritative urinary symptoms in association with vulvitis. Although three fourths reported being treated for vaginitis prior to developing dyspareunia, none related symptoms consistent with vaginitis or showed evidence of *Candida*, *Trichomonas*, or nonspecific vaginitis on pelvic examination or microscopic study at the time of our initial evaluation.

Table III. Results of local cryotherapy in 21 patients with focal vulvitis compared with 43 untreated patients*

Unimproved	11	52	20	47

*None of these differences are statistically significant at $p < 0.05$.

Less than half the patients related a history of recurrent aphthous stomatitis ("canker sores") or experiencing recurrent "cold sores" consistent with herpes labialis. Even fewer related a history of recurrent oral or labial lesions in a sexual partner.

Combining the results of the microbiologic studies done in these nine patients with studies done on a sporadic basis in the other 58 patients shows that, of 11 patients tested, all had negative cultures for *Neisseria gonorrhoeae*; of seven patients tested for colonization by *Chlamydia trachomatis*, all had negative cultures; 13 (50%) of 26 patients screened had positive cultures for mycoplasmas, usually *Ureaplasma urealyticum*; and all 14 tested had negative cultures for herpes simplex virus. None of the nine women prospectively studied was found to be a vaginal carrier of β-hemolytic streptococci, *S. aureus*, or *Mycobacterium* sp.

Treatment. After our initial examination, patients were managed in one of three ways: (1) followed up without specific therapy other than treatment of unrelated medical problems, (2) treated with local cryotherapy with the goal of destroying the lesions, or (3) in selected cases, beginning in 1984, treated by surgical excision of the hymenal ring and contiguous vestibular mucosa and submucosa as described by Woodruff and Parmley.[1]

Nonspecific therapy. Before our initial evaluation, most of these patients had been treated with a variety of vaginal creams or systemic antibiotics, most often tetracyclines, ampicillin, or metronidazole, usually for suspected vaginitis, without experiencing relief of their symptoms. Nine patients had received a 7- to 10-day course of a tetracycline, prescribed in six patients because of recovery of *Mycoplasma* sp. in culture and in three, as early empiric therapy of the characteristic syn-

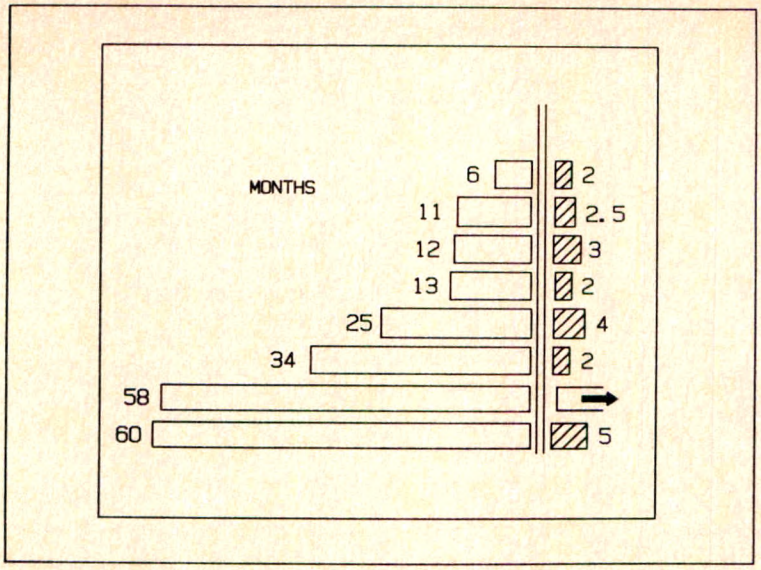

Fig. 6. Duration of symptomatic focal vulvitis before operation and length of disability after operation. In one of the eight patients, symptoms have continued unabated.

drome. Three of the nine patients experienced remission of their symptoms within 3 to 4 months, and one, 6 months later; two reported moderate improvement after treatment; the remaining four patients had no improvement. These data, similar to the natural history of the syndrome in untreated patients, do not suggest significant therapeutic benefit from the use of tetracyclines.

Cryotherapy. Twenty-two patients seen initially by one of us (J. J. P.) were treated with local cryotherapy aimed at destroying the focal areas of inflammation. None of the 45 patients managed by B. M. P. received cryotherapy. Comparison of the two contemporaneously managed groups reveals no significant differences in age at onset of the syndrome, parity, distribution of lesions, or duration of vulvitis.

Three patients did not return after their first visit and were lost to follow-up. Twenty-one evaluable patients received one to five (mean two) cryotherapy treatments of lesions and 43, no cryotherapy (Table III).

Among those treated with cryotherapy, eight (38%) became completely asymptomatic, two improved to the degree that they no longer felt the need for further treatment, and 11 (52%) remained unimproved. Of the eight that became asymptomatic, remission occurred in four during the first 6 months after therapy; in the remaining four, remission occurred more than 6 months later.

In the 43 untreated patients, 16 (37%) eventually had a complete spontaneous remission, seven (16%) reported partial improvement, and 20 (47%) remained unimproved. These results indicate that cryotherapy did not significantly affect the course of the disease.

Surgical excision. In 1983, Woodruff and Parmley[1] reported that surgical perineoplasty, consisting of resection of the hymenal ring and contiguous 0.5 cm of mucosa and submucosa had successfully alleviated the severe dyspareunia associated with this syndrome in 14 of 15 women operated on. To date nine of our patients have undergone this procedure. The results affirm the promising results of Woodruff and Parmley. Of the eight patients who have been followed up long enough for meaningful assessment of the therapeutic outcome (Fig. 6), seven who had been symptomatic from 6 to 60 months before operation are now asymptomatic and sexually active. One patient, symptomatic for 58 months before operation, remains a surgical treatment failure and is unable to have sexual relations without pain. One patient experiences occasional brief discomfort at intromission. The period of disability that follows successful operation, however, has never been less than 2 months and has lasted for as long as 5 months (Fig. 6).

Course of the disease. At the time of last contact, symptoms of the disease had persisted in 34 (51%) of the 67 patients. Twenty-four (36%) are in complete remission and nine (13%) have improved to the point that they no longer are seeking definitive therapy.

In two patients with continuing disease, the date of onset of symptoms is not known. The duration of symptoms for the remaining 32 patients ranges from 2 months to more than 18 years (Fig. 7). The severity of symptoms fluctuates. Discomfort is often worse in the week before menses. Some women have intermittent vulvar burning, which is precipitated or exacerbated by tight clothing.

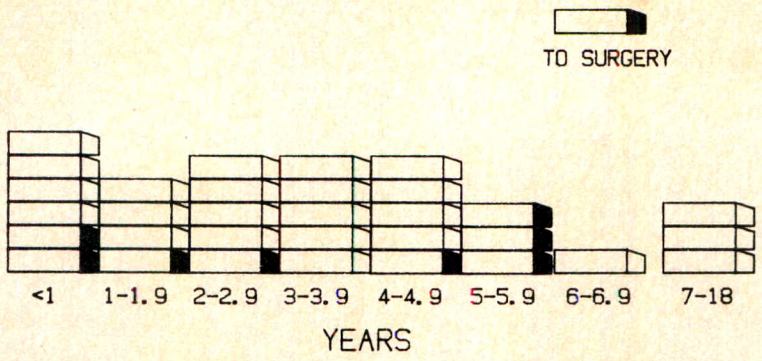

Fig. 7. Duration of symptoms at the time of last contact or the date of operation in 32 patients with continued focal vulvitis with dyspareunia.

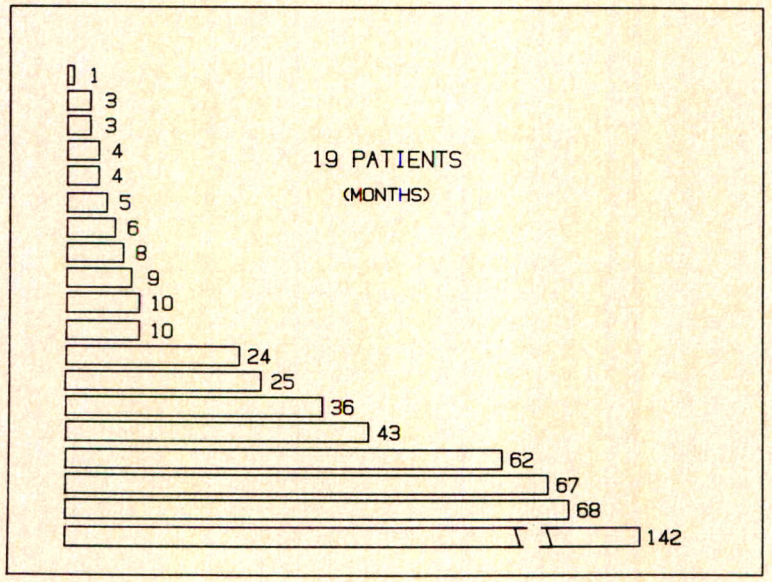

Fig. 8. Duration of symptoms of focal vulvitis at the time of complete spontaneous remission in 19 of 24 patients. In five patients complete data were not available.

Of the 24 women in complete spontaneous remission at the time of last contact, the date of onset of symptoms or the date of onset of remission is not available in five. In six of the remaining 19, the duration of symptoms at the time of remission was less than 6 months and remission was very rapid from its outset (Fig. 8).

In the remaining 13 patients now in complete remission, lesions and symptoms had persisted from 6 months to 12 years before remission. In most, improvement before complete resolution of all discomfort occurred only very gradually and has been difficult to time accurately.

Several patients who are free of pain at times other than intromission have learned to anesthetize the lesions with 4% aqueous Xylocaine with the aid of their sexual partners and enjoy comfortable intercourse. It is important that the Xylocaine be applied precisely, only to the painful lesions, with individual cotton-tipped applicators. These will be held in place automatically by the labia if the patient brings her legs together after the application. On removal of the applicators after 3 or 4 minutes, pain-free intercourse is usually possible for at least 10 to 15 minutes.

Pathologic findings. The surgical specimens from seven patients operated on at this institution were completely blocked for sectioning. In six cases, it was possible to accurately approximate the positin of each block on the vulva.

Unlike Robboy et al.,[11] who counted only those glands located "anterior to the vagina," we have counted all superficially located mucinous glands regardless of their position about the opening of the vagina (Fig. 9). Glands were found "anteriorly" (10 and 11 o'clock and 1 and 2 o'clock) in only two of the seven specimens. Posteriorly (3 through 9 o'clock), similar small glands were found singly or in multiples on one or both sides

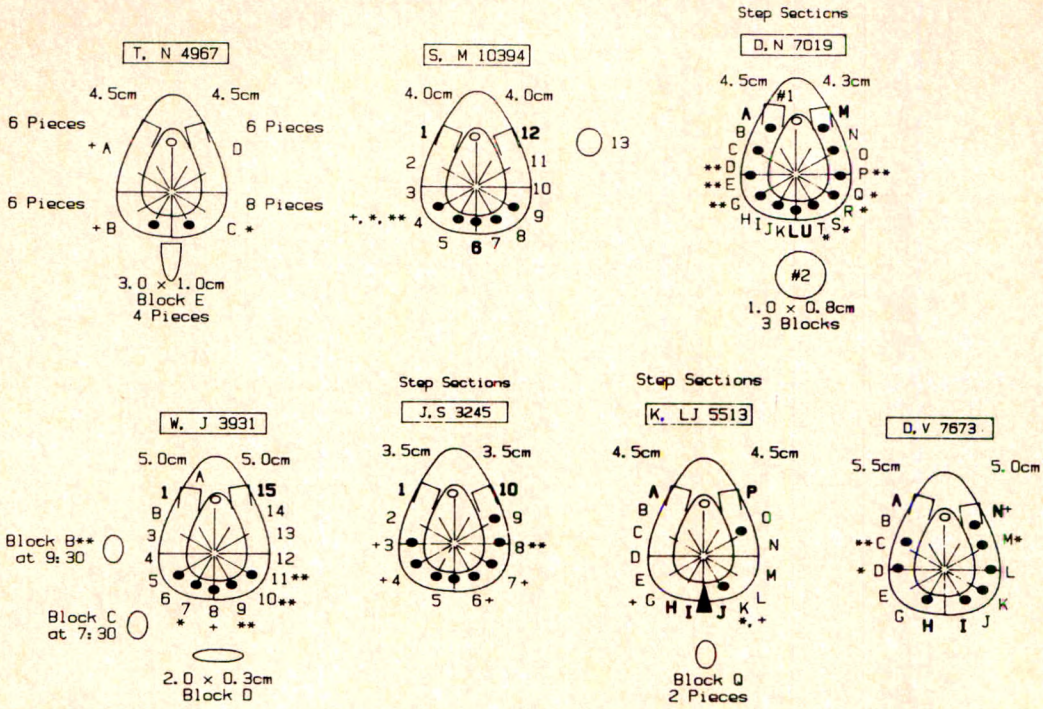

Fig. 9. The relationship of pathologic findings in serially blocked surgical specimens to vulvar lesions identified clinically. In each instance, the first block (designated as *A* or *1*) was taken from the apex of the arm of the Y- or U-shaped specimen on the patient's right. The positions of subsequent serial blocks, ascertained from the pathologic description, are indicated diagrammatically. When the exact location of an individual block is known, its position is indicated in *boldface type*. The remaining blocks have been assumed to be of equal size and have been distributed evenly between these known locations. To achieve a more complete sampling of the tissues, the original blocks from three specimens were reembedded in groups and were step sectioned after the routine sections had been made. The positions of the original lesions as identified at the initial examination are also diagrammatically displayed for each patient. * = Mucinous glands. ** = Mucinous glands associated with lymphocytic infiltration. + = Submucosal lymphocytic infiltration.

in all seven specimens examined; when many glands were found, the most common locations were between 3 and 5 o'clock and 7 and 9 o'clock. What appeared to be the opening of the duct of the major (Bartholin) gland was seen in the vicinity of these glands in only two specimens. No glands were seen in the area of the fourchette or perineal skin (6 o'clock) in any of the specimens.

Whether found singly or in groups, the numbers of inflammatory cells about these glands were not impressive (Fig. 9). Infiltration of the periglandular tissues by lymphocytes, occasionally associated with small numbers of plasma cells, was identified in five of the seven patients but never around all of the glands seen in the section.

Focal submucosal collections of lymphocytes unassociated with glands were seen in five of the seven specimens but were an impressive feature in only one. The epithelium over the most intensely infiltrated areas was usually thin and without papillary pegs. Perivascular infiltration by inflammatory cells, suggestive of vasculitis, was not seen in any of the sections examined.

The correlation between the locations of painful focal lesions and the sites of glands or focal infiltration by inflammatory cells on histologic examination of vulvar tissues from these patients is poor (Fig. 9).

Comment

We report a form of vulvitis characterized by severe and persistent superficial dyspareunia and the finding of one to 11 (median three) exquisitely tender, 3 to 10 mm areas of focal inflammation, with or without superficial ulcers, located on the mucosa of the vestibule. Three fourths of the lesions in 67 patients were located around the openings of the Bartholin ducts or between them posteriorly (Fig. 5), and 80% of the patients had lesions confined to this area. Based on our experience with 67 patients encountered during a 15-year period, we believe that this is a common cause of persistent, severe, superficial dyspareunia. Although adult women of all ages appear to be susceptible, the majority of cases have occurred in women in their 20s. Virtually all experience severe introital pain with intercourse; many have as a consequence become abstinent.

We believe that these patients are suffering from a condition described many years ago by several early observers,[4] including Kelly,[5] and independently rediscovered only recently by Woodruff and Parmley,[1] Friedrich,[2] and ourselves. We think the term focal vulvitis most simply and accurately describes the syndrome.

Woodruff and Parmley[1] and Friedrich[2] have recently provided a histopathologic description of these lesions, reporting infiltration about the minor vestibular glands of the vestibule by cells characteristic of chronic inflammation. In a careful histologic study of the surgical specimens from seven patients who were operated on (Fig. 9), we have counted all superficially located glands, regardless of their position about the opening of the vagina, by examining multiple sections from each of serial blocks of tissue. Neither these glands nor the focal areas of chronic inflammatory cells correspond closely with the lesions that were present in any given patient (Fig. 9). Moreover, the small numbers of lymphocytes seen about the glands in five of the seven specimens are not considered sufficient to indicate clear-cut glandular inflammation except in one patient.

Our failure to find large numbers of plasma cells in the hundreds of tissue sections examined would seem to exclude the possibility that the lesions we have described are the same as those described by Zoon[12] in men and designated "balanitis circumscripta plasmacellularis" and by others in women under a variety of names[13, 14]; the main distinguishing histopathologic feature of the lesions described in these reports is infiltration by large numbers of plasma cells.

We agree, however, with Woodruff and Parmley[1] that the painful lesions correlate best with what is probably endodermally derived mucosa, with or without glands, wherever it exists in the vestibule. Woodruff and Parmley[1] suggest that, with individual variation, only a portion of the epithelium covering the vestibule is of endodermal origin, that covering the fourchette and the inner surfaces of the labia minora, and offer as support the extreme sensitivity of the epithelium in these areas to 5-fluorouracil used in the treatment of vaginal carcinoma in situ. We have also noted, when using 5-fluorouracil in the vagina, that the most severe reaction occurs posteriorly, between 4 and 8 o'clock, and the least severe, anteriorly, between 9 and 3 o'clock, suggesting a smaller proportion of sensitive endodermally derived epithelium in these areas. Less endodermally derived epithelium in these areas might explain the infrequency of lesions in these areas (Fig. 3) as well as the relative rarity of minor vestibular glands between 10 and 2 o'clock as noted by us (Fig. 9) and reported by Robboy et al.[11] Epithelial primacy in pathogenesis might also explain the high frequency of lesions seen at 6 o'clock and their more diffuse character and the absence of vestibular glands seen in tissue sections from this area.

The relatively minimal histologic findings we report and others have described do not point toward any clear-cut cause. The normal appearance of the vagina, the clinical features of the lesions, and the negative microbiologic studies make it unlikely that this is an unusual form of vaginitis or an infection caused by herpes simplex virus, *N. gonorrhoeae*, *S. aureus*, β-hemolytic streptococci, *C. trachomatis*, mycoplasmas, or *Mycobacterium* sp. involving the mucosa, the submucosa, or the minor vestibular glands. The 50% rate of vaginal carriage of mycoplasmas in 26 of the women tested is comparable to carriage rates reported in asymptomatic, healthy, sexually active young women.[16] Moreover, we have been unable to obtain a history from any of our patients, including the nine studied in depth, to suggest that this is a transmissible disease; none of the women related a history of similar genital lesions in a sexual partner. And no evidence could be adduced that antimicrobial therapy received by many of these women, with a drug or drugs effective against the common agents of vaginitis, or against mycoplasmas or *C. trachomatis*, was of any demonstrable therapeutic benefit.

Based on the detailed sexual history obtained from nine of the women (Table II) it might be assumed that women developing this syndrome are sexually more active in terms of number of lifetime partners and oral-genital practices, but six of the 67 patients had the onset of this syndrome with first sexual intercourse. Future studies should include a case-control comparison of sexual practices in a large number of patients with the syndrome and asymptomatic control patients, matched for age, parity, and socioeconomic status.

It seems clear that this is not a manifestation of a systemic disease such as an autoimmune disorder or a vasculitis. It is possible that the cause will continue to be elusive, as has been the case with recurrent aphthous stomatitis.[17] Clearly, patients with focal vulvitis do not experience oral aphthous ulcers or herpes labialis more frequently than the population at large, nor do their sexual partners (Table II). Moreover, none of our patients have gone on to develop the classic constellation of oral-genital ulcers, inflammatory ophthalmologic lesions, and neurological disease characteristic of Behcet's syndrome.[18]

Given the nonspecific histopathologic findings and the negative results of studies to identify an infectious or autoimmune etiology, the condition we describe must continue to be regarded as a syndrome. Accordingly, with the lack of a reliable diagnostic laboratory test or characteristic histopathologic features, there is some hazard of misdiagnosis by the clinician. However, if other causes of acquired superficial dyspareunia such as hymenal tears, mucosal splits or abrasions (which

usually heal rapidly), Bartholin's cyst or abscess, herpes progenitalis, and vaginitis are excluded, if severe dyspareunia has persisted for a number of months, and if the characteristic exquisitely sensitive, highly focal lesions in the posterior vestibule have been clearly and repeatedly identified, we believe this syndrome can be diagnosed quite accurately.

The patient can aid in establishing the diagnosis by confirming the very focal nature of the lesions. If she can be taught to reliably identify and locate the lesions with a mirror or the aid of her partner and to anesthetize them locally with 4% Xylocaine, comfortable sexual relations should be possible.

Our early attempts to cure this syndrome with local therapy, including cryotherapy, have been unsuccessful. However, the highly focal nature of these lesions should encourage further investigation of alternative methods of local ablation with the goal of avoiding the expense, risks, and inconvenience of surgical excision, as described by Woodruff and Parmley,[1] which promises to provide definitive relief in most cases. Laser therapy appears to have been successful in patients with superficial dyspareunia when focal lesions are few and well localized.[15] The surgical procedure described by Munsick,[8, 9] which has been used for a variety of conditions causing dyspareunia, may well be of value for some patients with focal vulvitis but, like laser therapy, should also be carefully studied. We think that it is very likely that some of the patients Munsick has treated have been patients with unrecognized focal vulvitis.

Approximately one half of patients with focal vulvitis will eventually experience spontaneous improvement, most often total remission, and in about one half of these patients this occurs within 6 months; thereafter the probability of remission for patients who remain symptomatic falls to <25%, and it appears that many of these patients will remain symptomatic indefinitely (Fig. 8). Surgical perineoplasty as described by Woodruff and Parmley[1] appears to be effective in most cases, but in our judgment should be reserved for those patients who have experienced unremitting dyspareunia of unknown cause associated with the characteristic focal inflammatory lesions for at least 6 months.

We appreciate the review of the manuscript provided by Dr. Carol Spiegel, Director of the Clinical Microbiology Laboratory and Assistant Professor of Microbiology, the University of Wisconsin Medical School.

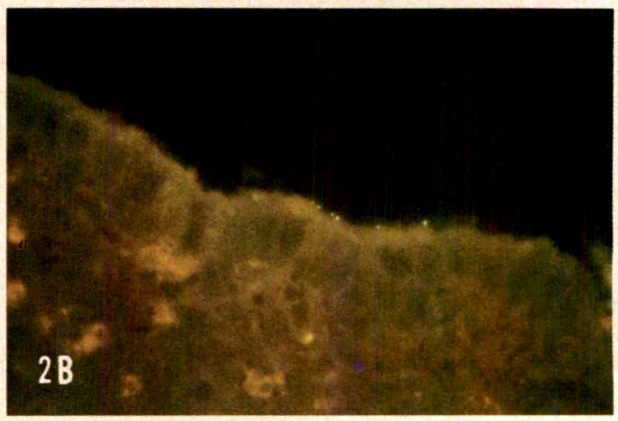
Localization of *Chlamydia trachomatis* infection by direct immunofluorescence and culture in pelvic inflammatory disease

Nancy B. Kiviat, M.D., Pål Wølner-Hanssen, M.D., Marcia Peterson, C.T., Judy Wasserheit, M.D., Walter E. Stamm, M.D., David A. Eschenbach, M.D., Jorma Paavonen, M.D., Julie Lingenfelter, C.T., Thomas Bell, M.D., Vinette Zabriskie, M.D., Barbara Kirby, M.D., and King K. Holmes, M.D., Ph.D.

Seattle, Washington

Fifty-five women with suspected pelvic inflammatory disease underwent diagnostic laparoscopy and endometrial and tubal biopsy, with specimens for isolation of *Chlamydia trachomatis* and for staining with a species-specific monoclonal fluorescein-conjugated antibody to *C. trachomatis* were obtained from the urethra, rectum, endocervix, endometrium, tubes, and cul-de-sac. *C. trachomatis* was isolated from 21 patients (38%), including 10 (18%) who had positive endometrial or tubal cultures. The fluorescein-conjugated antibody stain was positive for 43 (86%) of 50 culture-positive specimens, for 14 (18%) of 78 culture-negative specimens from 21 patients who had positive cultures from other sites, and for one (0.5%) of 192 specimens from 34 patients who had negative cultures at all sites. Thus the sensitivity of direct fluorescein-conjugated antibody for culture-positive specimens was 86% and the specificity for specimens from culture-negative patients was 99%. Twelve upper genital tract specimens were positive by fluorescein-conjugated antibody only. Fluorescein-conjugated antibody staining of 50 paraffin-embedded endometrial aspirates showed extracellular or intracellular elementary bodies and or cytoplasmic inclusions in all of seven culture-positive specimens, in four of six culture-negative specimens from patients who had positive cultures at other sites, and in none of 34 specimens from patients with negative cultures. Thus fluorescein-conjugated antibody staining is useful for confirming the role of *C. trachomatis* in endometritis and salpingitis. It is more sensitive than culture for detection of chlamydia in endometrial or tubal specimens and is able to confirm that the organism is actually present in endometrial tissue (rather than simply reflecting contamination from the cervix) in women with clinical evidence of pelvic inflammatory disease. (Am J Obstet Gynecol 1986;154:865-73.)

Key words: Diagnosis of *Chlamydia trachomatis,* pelvic inflammatory disease, monoclonal antibodies



C. trachomatis is now recognized as a leading cause of pelvic inflammatory disease.[1] However, diagnosis of chlamydial infection by culture is time-consuming and expensive, and methods for isolation in tissue cell culture are often unavailable. In addition, distinguishing endometrial infection from endocervical infection is confusing even when endometrial biopsy tissue is obtained for culture, because of possible contamination from the endocervix or vagina that may occur while endometrial samples are obtained. Among patients attending sexually transmitted disease clinics or family planning clinics, direct immunofluorescence has recently been shown to compare favorably with culture for diagnosis of genital chlamydial infection. Direct immunofluorescence staining of endocervical specimens, with a fluorescein-conjugated monoclonal antibody to *C. trachomatis,* had a sensitivity of 86% to 93% and a specificity of 93% to 99% as compared with those of isolation of the organism in tissue cell culture.[2, 3] To investigate the use of direct immunofluorescence for diagnosis of chlamydial infection in women with suspected PID, and to see if the method would allow us to more firmly establish a diagnosis of chlamydial endometritis and salpingitis, we collected multiple samples from upper and lower genital sites, as well as endometrial tissue biopsies, for culture and for immunofluorescent staining.

Material and methods

Study population. The study population included 55 consecutively studied women with lower abdominal pain and adnexal tenderness, presenting to the sexually transmitted disease clinic, emergency room or women's clinic at the Harborview Medical Center or the emergency room or women's clinic at the University Hospital. None had received antibiotics in the preceding 14 days.

Diagnosis of endometritis and salpingitis. A lapa-

roscopic diagnosis of acute salpingitis was made if there was erythema and edema of the fallopian tubes and either purulent exudate, fibrinous exudate, or fibrinous adhesions that could be readily broken. Diagnosis of endometritis was based on presence of at least 10 plasma cells per 120× field of endometrial tissue present.

Serologic studies. Serum was obtained on enrollment and all patients were asked to return at 2, 4-6, and 12 weeks after enrollment when serum was again obtained for analysis of acute and convalescent serum microimmunofluorescent total antibody and immunoglobulin M antibody to *C. trachomatis*. Acute sera and convalescent sera obtained 2 to 6 weeks after initial examination were available for testing from 39 patients.

Microbiologic studies

Specimen collection. Samples were obtained from the endocervix, urethra, rectum, endometrium, fallopian tubes, and cul-de-sac for culture and for fluorescent antibody staining for chlamydia. Endocervical cultures were obtained after the ectocervix had been wiped clear of vaginal discharge with large swabs. A type III calcium alginate swab or a cotton swab on a plastic shaft (Inolex, Glenwood, Illinois), from lots that were shown not to inhibit *C. trachomatis* growth in vitro, was introduced into the endocervical canal to obtain material for *C. trachomatis*. After the swab was rotated several times in the endocervical canal, it was placed in 1 ml of sucrose-phosphate chlamydia transport medium containing 2% fetal calf serum, 100,000 units of penicillinase, and 1 μg of gentamicin, 25 μg of vancomycin, and 25 units of nystatin. A second cotton-tipped swab was inserted and rotated in a similar manner and then used to smear endocervical material onto a glass slide, which was immediately fixed. Slides from the first 24 patients were fixed in 95% ethanol while slides from the last 31 patients were fixed in acetone (no difference in quality of staining related to these two fixatives was noted). An endocervical scrape was obtained with the rounded end of a wooden Ayre's spatula, and this material was likewise smeared onto a glass slide and placed in 95% ethanol. Rectal and urethral specimens were collected for *C. trachomatis* cultures and for slides for fluorescent antibody staining.

Under general anesthesia, patients then underwent endometrial aspiration and biopsy with a Novak curette. The endocervix was first prepared with a Betadine-alcohol swab. Endometrial material was aspirated through a Novak curette with a 10 ml syringe. Care was taken not to aspirate into the endocervical canal during removal of the curette. One drop of the curetted endometrial material was inoculated into transport media for culture for *C. trachomatis*. A second drop of material was smeared onto a glass slide and immediately fixed in 95% ethanol for up to 24 hours. The remainder of the endometrial tissue specimens were then fixed in buffered neutral formalin for histopathologic studies.

A laparoscopic examination was next performed, at which time any fluid present in the cul-de-sac was aspirated. One portion of the fluid was sent for culture for *C. trachomatis*, and the remainder was fixed in an equal amount of 95% ethanol or acetone for fluorescent antibody staining. If fallopian tubes were patent, an aluminum shaft calcium alginate swab was inserted through the laparoscope and introduced through the ostia 1 to 2 cm into the fallopian tubes. Material from the swabs was smeared onto slides for fluorescent antibody staining, as described above, and was also submitted for culture. If neither tube was patent a tube was punctured with an 18-gauge spinal needle and material was aspirated for culture and fluorescent antibody staining. Fimbrial biopsies were performed with a flexible esophageal pediatric biopsy forceps (Olympus Co., Tokyo) for histologic examination and fluorescein-conjugated antibody staining.

Isolation of C. trachomatis. Each specimen was inoculated into three wells of a 96-well microtiter plate as well as into two vials (one of which was used for secondary passage) containing cycloheximide-treated McCoy cells.[4] After 48 hours, cell layers were stained with fluorescein-conjugated monoclonal antibodies and examined for chlamydial inclusions.[5]

Fluorescent antibody staining of smears and tissue. Slides were removed from ethanol or acetone within 24 hours and if not immediately stained were frozen at −70° C for 1 to 2 weeks. Slides were stained as previously described[6] with fluorescein-conjugated monoclonal antibody to *C. trachomatis* (Syva Corp., Palo Alto, California). This antibody to the major outer membrane protein with a molecular weight of 40,000 dalton reacts with all 15 known serovars of *C. trachomatis* but not with *Chlamydia psittaci*. In 25 cases, 150 μl of solution containing antibody was applied to each slide. Slides were then incubated at room temperature for 30 minutes. In the remaining 30 cases, 100 μl of solution containing antibody was applied to each slide and the slides were then incubated for 15 minutes at room temperature. After removal of excess antibody, the slides were rinsed with ionized water and air dried. A combination of Tris buffer and glycerol was used as mounting medium and coverslips were placed on the slides. Slides were examined immediately without knowledge of other clinical, histologic, cytologic, or microbiologic findings. Specimens were examined with an 8× ocular lens and a 40× objective lens. The presence of elementary bodies of *C. trachomatis* and of typical chlamydial inclusions were confirmed with a 63× oil immersion lens. The location of elementary bodies (within inflammatory cells, within epithelial cells, and/or cell-free or at-

tached to red blood cells) was also carefully noted. Smears from the urethra were considered adequate only if glandular epithelial cells were present. Smears from the cervix were considered adequate only if they contained mucus. Slides from upper genital tract sites were rejected if they were completely devoid of any material. Slides were also rejected if the specimens were so thick it was impossible to discern cellular detail. After examination the smears were frozen to permit later reexamination to determine reproducibility.

Formalin-fixed endometrial tissue was routinely paraffin embedded; 4 μm sections were cut, deparaffinized, and stained as described above with 150 μl of antibody solution. Only specimens containing endometrial glandular epithelium were considered adequate for evaluation by fluorescein-conjugated antibody. All specimens were examined without knowledge of clinical or laboratory findings.

Two years after initial evaluation, all smears from the first 11 women who were found by either culture or fluorescein-conjugated antibody staining to have chlamydial infection were examined, along with an equal number of slides from corresponding sites from the first 16 patients who had negative cultures and negative fluorescein-conjugated antibody staining at all sites. All slides from these 27 patients were relabeled, restained with 150 μl of antibody-containing solution, and incubated for 30 minutes at 37° C. These were then reexamined by the original observer (who had more than 2000 hours of experience) as well as by a second, less experienced observer (who had only 80 hours of prior experience) to assess intraobserver and interobserver reproducibility.

Results

Correlation of culture and serologic results with presence of salpingitis and/or endometritis. On the initial review of 326 smears collected for fluorescein-conjugated antibody staining, 320 were considered adequate for evaluation. Endometrial tissue adequate for fluorescein-conjugated antibody staining was obtained from 50 of 55 patients who underwent endometrial aspiration. Twenty-one (38%) of the patients had positive cultures for *C. trachomatis* at one or more sites; 10 (18%) had positive endometrial or tubal cultures. The remaining 34 had negative cultures for *C. trachomatis* at all sites. Two patients with negative cultures had serologic evidence of acute chlamydial infection: One had serum immunoglobulin M antibody to *C. trachomatis* at the time of enrollment, and the second had a fourfold rise in total antibody titer to *C. trachomatis*. Overall, chlamydial infection was demonstrated by isolation of the agent from any site or by serologic results in 21 (58%) of 36 women with salpingitis and/or plasma endometritis and in two (11%) of 19 with neither salpingitis nor endometritis. None of the 19 women with neither salpingitis nor endometritis had *C. trachomatis* isolated or had positive fluorescein-conjugated antibody staining at the endometrial, tubal, or cul-de-sac sites.

*Results of culture and staining of endometrial smears and endometrial biopsy specimens are grouped for each patient.

Correlation of direct immunofluorescent staining with culture results. Fifty-five specimens from 21 patients were culture positive and 58 smears from 22 patients were fluorescein-conjugated antibody positive for *C. trachomatis*. In smears, elementary bodies were seen free, within polymorphonuclear leukocytes and histiocytes, or attached to the surfaces of glandular cells or red blood cells. Intraepithelial inclusions were seen by fluorescein-conjugated antibody in only four of 18 cervical smears (all of which also contained elementary bodies seen by fluorescein-conjugated antibody). Smears from the rectum, urethra, endometrium, fallopian tubes, and cul-de-sac demonstrated only elementary bodies. Examples of cervical smears that do and do not show elementary bodies and inclusions are shown in Fig. 1, *A* and *B*. Larger organisms, which showed peripheral immunofluorescent staining characteristic of chlamydial reticulate bodies, were occasionally seen but only in association with elementary bodies.

Table I compares the results of culture and fluorescein-conjugated antibody stain by site for each of the 22 women with positive cultures and/or fluorescein-conjugated antibody tests at any site. A disagreement between culture and fluorescein-conjugated antibody staining occurred at one site in six patients, at two sites in three patients, and at five sites in two patients. Among the seven patients with discrepancies between cultures and immunofluorescent staining of an upper tract site (positive immunofluorescence with negative culture in all seven), three had a positive culture for *C. trachomatis* at another upper tract site, and three had positive cultures for *C. trachomatis* only from the lower genital tract or rectum, while one had no positive cultures but did have serum immunofluorescent antibody to *C. trachomatis* in a persistently elevated titer of 1:512. All seven had salpingitis.

Table II summarizes the results of all cultures and fluorescein-conjugated antibody stains by site in all 55 patients. The fluorescein-conjugated antibody stain was positive for 43 (86%) of 50 culture-positive specimens, 14 (18%) of 78 culture-negative specimens from patients who had positive cultures at other sites, and one (0.5%) of 192 specimens from patients who had negative cultures at all sites. This latter patient had a serum microimmunofluorescent antibody titer of 1:512 against *C. trachomatis*. Among the 65 specimens that were positive by culture and/or immunofluorescence, those positive by immunofluorescence alone accounted for three of 40 from the lower genital tract or rectum versus 12 of 25 from the endometrium, fallopian tubes, or cul-de-sac ($p \leq 0.001$). Specimens positive by culture only accounted for seven of 40 positive results by either method from the lower tract versus none of 25 results from the upper tract ($p \leq 0.02$). Thus, of 25 upper-tract specimens that were positive by either method, *C. trachomatis* was detected by culture in 13 specimens and by immunofluorescence in 25 specimens.

All lower- and upper-tract fluorescein-conjugated antibody smears that disagreed with culture were then reviewed by three observers. On review of 15 specimens

Table III. Results of culture and direct immunofluorescence for *C. trachomatis* in 320 specimens from 55 patients, stratified on the basis of presence or absence of laparoscopic evidence of salpingitis or histologic evidence of plasma cell endometritis

Site tested by laparoscopic findings	*Culture positive, fluorescein-conjugated antibody positive*	*Culture positive, fluorescein-conjugated antibody negative*	*Culture negative, fluorescein-conjugated antibody positive*	*Culture negative, fluorescein-conjugated antibody negative*
Laparoscopic evidence of salpingitis or endometritis (n = 36 patients)*

Lower-tract sites	28	6	3	57
No laparoscopic evidence of salpingitis or endometritis (n = 19 patients)†				
Upper-tract sites	0	0	0	62
Lower-tract sites	2	1	0	55

*Ten patients had salpingitis only, two had endometritis only, 22 had both salpingitis and endometritis, and two had an endometrial biopsy specimen that was inadequate for histologic examination.

†One patient had an endometrial biopsy specimen that was inadequate for histologic examination.

that were initially interpreted as fluorescein-conjugated antibody positive and culture negative, 10 showed typical elementary bodies, two showed no elementary bodies, and three were considered inadequate after restaining, as discussed below. An unblinded review of the seven negative fluorescein-conjugated antibody smears from culture-positive sites was then performed without restaining. On one urethral smear, three poorly stained elementary bodies were then located. In addition, it was noted that one smear had been stained on the reverse side. The smear was positive after the correct side was stained. One cervical smear failed to show any elementary bodies. All four remaining negative fluorescein-conjugated antibody smears from culture-positive sites had initially been stained with 100 μl of antibody solution for 15 minutes. When these four smears were restained with 150 μl of antibody solution for 30 minutes, all four were found to contain elementary bodies.

Immunofluorescent staining of paraffin-imbedded endometrial biopsies. Fifteen of the 50 paraffin-imbedded endometrial biopsy specimens considered adequate for evaluation were positive by immunofluorescent staining for *C. trachomatis* elementary bodies. Endometrial aspirate cultures were positive for seven of the 11 patients whose endometrial biopsy specimens did show *C. trachomatis* by immunofluorescence versus none of 35 whose biopsy specimens did not show *C. trachomatis* by immunofluorescence. Of the four patients with positive fluorescein-conjugated antibody biopsy specimens who had negative endometrial aspiration cultures, all had positive cultures from other sites, three had characteristic, fluorescein-conjugated antibody–positive chlamydial inclusions within endometrial cells and all had typical elementary bodies of *C. trachomatis* detected by immunofluorescence in endometrial biopsy specimens and smears.

The elementary bodies were located on the surfaces of and within endometrial epithelial cells and in polymorphonuclear leukocytes and histiocytes. In eight of 11 patients whose endometrial biopsy specimens showed elementary bodies, scattered typical inclusions were also found in from one to 70 surface glandular cells, representing fewer than 1% of glandular cells present on the sections reviewed. Elementary bodies were also seen attached to the surface epithelium adjacent to inclusions in all cases where inclusions were seen (Fig. 2, *A* and *B*).

Immunofluorescent staining and culture of fimbrial biopsy specimens and endosalpingeal smears or brushes. Endosalpingeal brushes or smears were available from 28 women for comparison of immunofluorescent staining and culture. Endosalpingeal brushes or smears were positive for *C. trachomatis* (by both fluorescein-conjugated antibody stain and culture) in three cases (P010, P016, and ICD9). An example of an endosalpingeal smear showing elementary bodies of *C. trachomatis* associated with a polymorphonuclear leukocyte is shown in Fig. 3. The fimbrial biopsy specimen was positive (by both fluorescein-conjugated antibody stain and culture) in only one case (P010). One additional patient (P022) underwent salpingo-oophorectomy for tuboovarian abscess; *C. trachomatis* was demonstrated by fluorescein-conjugated antibody stain but not by culture in tubal tissue and aspirated tubal pus from this patient.

Correlation of immunofluorescent staining and culture with laparoscopy. Table III shows the results of culture and direct immunofluorescent stain for *C. trachomatis* stratified by the presence or absence of salpingitis or endometritis. All of the 15 fluorescein-conjugated antibody–positive, culture-negative specimens occurred in patients with laparoscopic evidence of salpingitis. Twelve occurred in upper-tract sites, and three

in lower-tract sites. All of the seven culture-positive, fluorescein-conjugated antibody–negative specimens were from lower-tract sites, and six occurred in patients with laparoscopic evidence of salpingitis. Overall, among 36 women with pelvic inflammatory disease, upper-tract specimens revealed chlamydia by fluorescein-conjugated antibody stain alone in four women, by culture alone in none, and by both methods in eight women (Table I).

Intraobserver and interobserver reproducibility in interpretation of immunofluorescent staining. Table IV shows the intraobserver reproducibility as assessed by the original observer after slides were restained with 150 ml of antibody-containing solution and incubated for 30 minutes at 37° C. Of 98 specimens that were restained and rescreened, 95 were felt to be satisfactory for review. Fifty-seven smears were called negative on both examinations; 29 were called positive on both examinations; six were called negative, then positive (as described above, all sites were positive by culture and all slides had originally been stained with only 100 ml of antibody, one on the wrong side of the slide, and incubated for only 15 minutes at room temperature); six were initially called positive, then subsequently called negative or inadequate. Of the three that were initially positive, then negative, a final unblinded review disclosed definite elementary bodies in one. Of three that were initially positive, then inadequate, all were from a single patient and showed background fluorescence after restaining. In summary, there was 87% intraobserver reproducibility, despite possible problems attributed to restaining and to initial use of protocol for fluorescein-conjugated antibody staining that may not have been optimal.

Table V shows the results of interobserver reproducibility as assessed on restained slides. Of 97 slides considered adequate for evaluation by both observers, 58 were called negative by both observers, 27 were called positive by both, and there was disagreement on 12 of the specimens. Thus interobserver reproducibility was also 87%. The more experienced observer agreed with culture in 11 of the 12 interobserver disagreements, while the less experienced observer agreed with culture in one of the 12 interobserver disagreements. A final joint review of the cases on which there was disagreement was then performed with the observers blinded as to culture results and their original classification of the slide. In all cases, the final diagnoses were similar to the original diagnosis of the more experienced observer, and in all but one case the final diagnosis was in agreement with culture results at that site.

Comment

In this comparison of conventional culture techniques with direct immunofluorescence with the use of fluorescein-conjugated monoclonal antibodies for detection of *C. trachomatis*, we found that when specimens were regarded as positive if either culture or initial fluorescein-conjugated antibody examination was positive, in lower-tract sites the sensitivity of culture (92%) was higher than that of direct fluorescein-conjugated antibody (83%), whereas for specimens from the endometrium and tubes the sensitivity of direct fluorescein-conjugated antibody (100%) was substantially higher than that of culture (52%). Several factors may be responsible for the lower sensitivity of culture for upper-tract specimens. Infections in upper-tract sites may result in production of specific or nonspecific toxins that interfere with culture. Several studies have shown that whole sera can to some extent neutralize homologous strains of chlamydia.[7, 8] Caldwell and Perry[9] and Peeling et al.[10] noted that antibodies to the major outer membrane protein of *C. trachomatis* (MOMP) could neutralize homologous strains in vitro and that neutralization occurred after endocytosis of the organism, perhaps by promoting phagolysosomal fusion or prevention of intracellular differentiation. Howard[11] showed that neutralization titers of serum antibody were increased by the addition of complement. In the upper tract and especially in the endometrium, where subepithelial hemorrhage is frequently seen adjacent to intracellular chlamydial inclusions, complement, complement-fixing antibody, and perhaps antibody having other functions may be more available than in lower-tract sites and may result in more effective neutralization of organisms. Thus the organisms noted in the upper tract may or may not have been viable at the time of sampling. In addition, surgical procedures, for example, cleaning the cervix with Betadine before endometrial biopsy, could also have interfered with isolation of chlamydia from the upper tract.

The specificity of direct immunofluorescent staining for *C. trachomatis* appears to be high. Fourteen of the 15 culture-negative, fluorescein-conjugated antibody–positive specimens came from patients who had positive cultures at other sites, and the remaining patient had high titers of serum antibody to chlamydia. Among patients who had negative cultures at all sites, the specificity of direct fluorescein-conjugated antibody staining of all specimens was 191 of 192, or 99%. Among the culture-positive specimens, the sensitivity of initial fluorescein-conjugated antibody stain in comparison with culture was 82% for staining with 100 μl of antibody for 15 minutes and 97% for staining with 150 μg for 30 minutes. We therefore have continued to use the latter method. The sensitivity of fluorescein-conjugated antibody staining was lowest for specimens from the urethra and rectum. This may have been related to the concentration of organisms present, to the amount of material collected (collection of adequate material from the rectum and urethra may be more difficult than from other sites), and to the initial use of a staining method that was not optimal in some cases.

Both intraobserver and interobserver reproducibility was 87%. In several cases the intraobserver variability was due to technical problems, such as staining the wrong side of the slide or inadequate counterstaining with the second restaining, or to use of a lower concentration of antibodies with the initial staining, as discussed above. It may also be that repeated washing of the slides during restaining resulted in loss of elementary bodies or that fewer antigenic sites were available for antibody binding after restaining.

Fimbrial biopsy did not increase the detection of *C. trachomatis* in this study, perhaps because of the small amount of tissue examined. All verified tubal chlamydial infections were demonstrated by examination of endosalpingeal brushings or aspirated tubal pus.

The use of monoclonal antibodies on endometrial tissue with identification of the organism within endometrial glandular epithelium, within inflammatory cells, within glandular epithelium, or in underlying endometrial stromal cells allows one to distinguish true endometrial infection from contamination of the endometrial cavity that might result when swabs or curettes are introduced into the uterus through the infected cervix. In the present study, staining of paraffin-embedded endometrial tissue with monoclonal antibody to *C. trachomatis* detected all infections demonstrated by culture and several not demonstrated by culture. Endometrial biopsy also permits confirmation of the presence of endometritis.[8] Thus endometrial biopsy for conventional histologic studies and immunofluorescent staining should be useful in the future for establishing the diagnosis of chlamydial endometritis.

Obstetric hospital stays by diagnosis related groups: A community-based analysis

Ronald J. Lagoe, Ph.D.
Syracuse, New York

The study analyzed obstetric inpatient hospital stays by diagnosis related group in Sacramento, California, and Syracuse, New York, two areas with similar admission rates, between 1981 and 1984. The sample included 123,308 hospital discharges. The data indicated that aggregate obstetric stays in Syracuse were 32.9% longer than those in Sacramento, which was typical of differences between these stays in the western and northeastern United States. Obstetric stays in both areas declined between 1981 and 1984; however, the rate of decline in Sacramento (6.1%) was substantially higher than that of Syracuse (3.5%). Variability of obstetric stays was substantially lower in Syracuse for most diagnosis related groups, including those with the largest caseloads. These results suggest that community and regional differences in obstetric hospital stays may be produced by system-wide consumer preferences and physician practice patterns, more than by hospital bed availability, health maintenance organization activity, or other factors. (Am J Obstet Gynecol 1986;154:873-8.)

Key words: Obstetrics, delivery, hospitalization, utilization review

The implementation of new hospital reimbursement systems based on diagnosis related groups (DRGs) is focusing increased attention on reduction of acute care stays in the United States. Under these systems, each hospital inpatient is assigned to one of 468 DRGs, which are defined by the individual's principal operating room procedure, principal diagnosis, presence or absence of comorbidities and complications, age, sex, and discharge status.[1] Obstetric patients are assigned to DRGs 370 to 384. Specific categories concern admission for cesarean section (DRGs 370 and 371), vaginal delivery (372 to 375), postpartum diagnoses (376 and 377), ectopic pregnancy (378), threatened abortion (379), abortion (380 and 381), false labor (382), and antepartum diagnoses (383 and 384).[2] Hospitals receive a relatively fixed payment for each discharge in each DRG. A limited additional payment is frequently provided for patients with extremely long stays or inordinately high costs; however, such reimbursement does not approximate the costs of providing acute care.[3]

DRGs were adopted by the federal Health Care Financing Administration for Medicare reimbursement during 1983. Since that time, hospital stays for medicare patients have declined by 6%.[4] Obstetric hospital stays are generally reimbursed through Medicaid, Blue Cross, or commercial insurance. A number of states, including New Jersey, Michigan, Ohio, Pennsylvania, Utah, and Washington, have implemented Medicaid reimbursement systems based on DRGs.[5] Blue Cross plans in various areas of the nation and commercial insurance companies have also implemented DRG-based reimbursement.[6] Connecticut has become one of the first states to employ the federal DRGs for all major payers.[7]

Historically, obstetric hospital stays in the United States have varied substantially by region. Stays have generally been shortest in the western part of the nation and longest in the northeastern and southern regions.

Table I. Hospital lengths of stay: Obstetric DRGs—total

	Mean annual discharges	*Inpatient mean stays*			
		1981	*1982*	*1983*	*1984*
Sacramento	19,731	2.63	2.50	2.49	2.47
Syracuse	11,096	3.40	3.41	3.29	3.28

In 1977, obstetric mean hospital stays ranged from 2.8 days in the West to 3.9 days in the Northeast, a difference of 39.2%, in comparison with 3.5 days for the entire nation.[8] In 1982, regional mean stays for specific obstetric procedures and diagnoses with the highest frequencies were also shortest in the West and longest in the Northeast. Stays for vaginal delivery without complicating diagnoses ranged from 2.2 days in the West to 3.4 days in the Northeast, a difference of 54.5%, in comparison with a national mean of 2.9 days. Mean stays for cesarean section without substantial complications ranged from 4.8 days in the West to 6.7 days in the Northeast, a difference of 39.6%, in comparison with a national mean of 5.7 days.[9]

Available literature suggests that these and other variations in regional hospital stays may be produced by factors such as the greater availability of hospital beds in the Northeast,[10] the high use of health maintenance organizations in the West,[11] or consumer preferences and physicians' practice patterns.[12] It has also been suggested that the implementation of DRGs by a full range of payers may reduce hospitals stays for the entire nation to levels currently experienced in the West.[13] Obstetricians have also predicted reductions in hospitalization for many of their patients.[14]

However, research has not focused on regional variations in obstetric hospital stays. National studies of major metropolitan areas, such as the work of Knickman and Foltz,[15] have concerned aggregate hospital utilization rather than stays for individual services such as obstetrics. Most of the so-called small-area studies, such as those performed by Wennberg et al.[12, 16] in Maine and Iowa, have evaluated differences in discharges and patient days per thousand, rather than stays, for specific procedures.

This study compared hospital mean stays for obstetric inpatients by DRG category in two U.S. metropolitan areas, Sacramento, California, and Syracuse, New York. These areas are located in the West and Northeast, respectively, the regions that have produced the widest variations in obstetric inpatient stays during recent years. The analysis identified variations and obstetric stays by DRG category and suggested possible causes of these differences.

Method

The study focused on inpatient lengths of stay and related aspects of hospital utilization for obstetric DRGs in Sacramento, California, and Syracuse, New York, during the calendar years 1981 to 1984. These DRGs, which are contained in Major Diagnostic Category (MDC) 14, were defined according to the Yale School of Organization and Management's DRG classification system, first revision.[2]

Sacramento and Syracuse were selected as the areas for the study because they had similar hospital utilization characteristics and resource availability. Total hospital admissions per 1000 population in 1984, 129.56 (Sacramento) and 130.17 (Syracuse), varied by less than 1%. Hospital bed availability per 1000 population in 1984 was also similar: 3.05 (Sacramento) and 2.91 (Syracuse). Percentages of inpatient populations less than 65 years of age differed by 2 points: 78.3 (Sacramento) and 80.1 (Syracuse). Each area also contained a medical school hospital and at least three community hospitals (Hospital Executive Council of Syracuse, unpublished data).

Hospital utilization data for the calendar years 1981, 1982, 1983, and 1984 were collected by the acute care planning organization in the respective areas, the Sacramento-Sierra Hospital Association and the Hospital Executive Council of Syracuse. All 11 Sacramento general hospitals and all four Syracuse hospitals furnished utilization data. This information was processed into DRG data through use of a standard first-revision "Grouper" program, International Classification of Diseases, Adapted, ed. 9, Clinical Modification (ICD-9-CM). A total of 123,308 discharges in the sample metropolitan areas were identified through these activities.

The initial analysis of the data focused on comparison of discharge levels and mean stays for the combined obstetric DRGs in the two areas. Subsequent analyses focused on mean stays and length-of-stay coefficients of variation for each DRG in the two areas. Coefficients of variation (standard deviation divided by mean) were employed to compare variability of stays in order to control for the influence of mean stay levels.[17]

Results

The initial section of the analysis focused on inpatient discharges and mean stays for the combined obstetric DRGs in the two metropolitan areas. Related data are summarized in Table I.

This information indicated that obstetric lengths of stay in Sacramento and Syracuse generally reflected differences between stays in the western and north-

Steril./D&C = sterilization/dilation and curettage; OR = operating room; ex. = except.

eastern United States that have been identified in the literature.[8, 9] Most of the differences in hospital utilization between the two metropolitan areas could be attributed to variations in lengths of stay rather than admissions. Mean annual obstetric hospital admissions and discharges per 1000 population ranged from 19.57 in Sacramento to 19.97 in Syracuse during the 4-year period, a difference of only 2.0%. At the same time, the mean inpatient stay for Syracuse (3.35 days) exceeded the mean for Sacramento (2.52 days) by 32.9%.

The data also indicated that mean obstetric stays declined in both areas between 1981 and 1984. With the exception of the years 1981 and 1982 in Syracuse, a steady progression of year-to-year reductions in stays occurred in both areas. Stays in Sacramento dropped by 6.1%, whereas stays in Syracuse fell by 3.5%. It should be noted that the rate of decline in Sacramento, the area with shorter stays through the period, was almost double that of Syracuse.

The remainder of the study focused on analysis of differences between obstetric hospital stays in the two areas by DRG category. Data concerning DRGs 370 to 377, which concern deliveries and postpartum diagnoses, are summarized in Table II.

Table III. Hospital lengths of stay: Obstetric diagnosis related groups 378 to 384

	Mean annual discharges	*Inpatient mean stays (stay coefficients of variation)*

		(0.94)	(1.50)	(1.26)	(1.22)

D&C = Dilation and curettage.

These data indicated that obstetric DRGs, which included delivery (Nos. 370 to 375), accounted for a substantial majority of all obstetric admissions in both areas, 78.9% of the total in Sacramento and 73.7% of the total in Syracuse. Among obstetric DRGs involving delivery, mean stays for Syracuse, the northeastern community, generally exceeded those of Sacramento. Differences between hospital stays in DRGs with the largest caseloads were substantial. For normal vaginal delivery (DRG 373) the combined average stay for 1981 to 1984 in Syracuse exceeded that of Sacramento by 39.4%, whereas the combined average for cesarean section without comorbidities or complications (DRG 371) in Syracuse exceeded that of Sacramento by 30.5%. Similar differences in stays characterized postpartum diagnoses. These differences were typical of regional variations in stays.

The data also indicated that mean hospital stays for delivery and postpartum DRGs progressively declined in both areas between 1981 and 1984. Reflecting trends in total obstetric stays, however, stays in Sacramento fell more rapidly than those in Syracuse. Rates of decline for DRG 371 and DRG 373 stays in Sacramento, about 16%, were approximately double those of Syracuse.

Perhaps most interesting were the relationships between mean stay levels and variability of hospital stays, as measured by coefficients of variation, which appeared in the data. This information indicated that length of stay variability in Syracuse was comparable to or less than that in Sacramento for most of the DRGs evaluated. Between 1981 and 1984, coefficients of variation for Syracuse averaged lower than those for Sacramento in all categories involving delivery except DRG 370, where they were essentially equal. Variability of stays was also lower in Syracuse for postpartum diagnoses. Coefficients of variation for postpartum diagnoses with operating room procedures (DRG 377) were substantially higher in both areas than coefficients for other DRGs, indicating that this category included patients with an extensive range of hospital stays.

The second portion of the DRG-specific section of the study focused on categories involving problem pregnancies, other antepartum diagnoses, and inpatient abortions. Related data are summarized in Table III.

These combined categories accounted for 20% to 25% of total obstetric admissions in the two metropolitan areas. Utilization varied between the two areas. Admission levels were highest for abortions with curettage (DRG 381) in Sacramento and for other antepartum diagnoses with complications (DRG 383) in Syracuse. Mean stays in Syracuse generally exceeded those in Sacramento for DRGs involving ectopic pregnancy, abortions, and antepartum diagnoses without complications. However, mean stays in Sacramento generally exceeded those in Syracuse for DRGs involving false labor and antepartum diagnoses with complications. The data did not suggest any relationships between these two groups of DRGs, especially with regard to antepartum diagnoses.

The data indicated that hospital stays for a number of these DRGs declined between 1981 and 1984, although such reductions were not as prevalent as among DRGs involving delivery and postpartum diagnoses. Over the period of the study, mean stays declined in Sacramento but increased or remained stable in Syracuse in DRGs 379, 380, 382, and 384.

These trends in hospital mean stays did not appear to be related to data concerning variability of stays. For the 4-year period, average coefficients of variation were lower in Syracuse for all of these DRGs except No. 378, where they were essentially equal, and for No. 383, where Sacramento coefficients were lower. Coefficients of variation for both areas were especially high in DRG 384, indicating that this category included patients with an extensive range of hospital stays.

Comment

As DRG-based hospital payment systems are implemented for Medicaid, Blue Cross, commercial insurance, and other private payers, it seems that probable increased attention will focus on reduction of obstetric inpatient stays. Obstetric cases constitute a major portion of the claims volume among these payers. Although wholesale elimination of obstetric stays through extensive use of birthing centers may remain a long-term goal, short-term utilization initiatives will probably concentrate on length-of-stay reduction, particularly in the northeastern United States.

This comparison of obstetric stays by DRG focused on two metropolitan areas with acute care bed availability substantially below national levels. As hospital bed reduction proceeds in the rest of the nation, the experience of Sacramento and Syracuse areas may anticipate national trends. The analysis identified substantial differences in obstetric hospital mean stays between these two areas. These differences reflected the longer hospital stays that have marked obstetric utilization in the northeastern United States. Utilization data indicated that although stays declined in both areas between 1981 and 1984, the rate of decline in Sacramento was almost double that of Syracuse. Syracuse stays fell at a lower rate in DRGs involving delivery and postpartum diagnoses and remained stable or increased in other categories. If these trends are representative of regional patterns, it appears that the gap between obstetric stays in western and northeastern United States may be widening.

The analysis also provided some information concerning the causes of these differences in stays. The data indicated that acute care bed availability and admission rates were not responsible for length-of-stay variations, since these levels were essentially the same in Sacramento and Syracuse. HMO penetration in Sacramento was substantially higher than in Syracuse. However, the data also suggested that greater uniformity of physician practice, typically generated by extensive use of health maintenance organizations and other utilization control mechanisms, was probably not a major factor, since length-of-stay variability in Syracuse was lower than that of Sacramento for a substantial majority of the DRGs evaluated. Instead, the differences in mean stays appeared to have been produced by more conservative consumer preferences and physician practice patterns in the Northeast. It was notable that in most obstetric DRGs, especially the high-volume delivery categories, these discharge patterns were less variable than the approaches that produced shorter stays in Sacramento. It is possible that these trends limited the rate of obstetric stay reduction in Syracuse and the Northeast.

These results indicate that regional differences in obstetric stays may be less subject to change than was previously thought. Unlike hospital bed availability and health maintenance organization penetration, which have evolved fairly rapidly in recent years, the behavior of consumer and physician communities will be more difficult to change. The extension of DRG-based hospital reimbursement may help bring this about. However, national uniformity of obstetric hospital stays may not be as close as some would believe.

An epidemic of maternal thrombocytopenia associated with elevated antiplatelet antibody

Platelet count and antiplatelet antibody in 116 consecutive pregnancies: Relationship to neonatal platelet count

David Hart, M.D., Carol Dunetz, M.D., Michael Nardi, M.S., Robert F. Porges, M.D., Agnes Weiss, M.D., and Margaret Karpatkin, M.D.

New York, New York

Twenty-eight (24%) of 116 pregnant women studied prospectively during an 8-month period in 1983 had platelet counts of <150,000/mm³ at least once during pregnancy. Thirteen of these were thrombocytopenic in both the prenatal and the peripartum period. Eighteen were restudied 3 to 12 months after delivery. One woman, who was pregnant again, had a platelet count of 140,000/mm³. In the others, platelet counts were in the normal range. Platelet-associated immunoglobulin G and serum antiplatelet antibody levels were elevated in 79% and 61%, respectively, of these 28 women on at least one occasion. However, 59% of 73 pregnant nonthrombocytopenic women had increased platelet-associated immunoglobulin G levels and 59% had positive serum antiplatelet antibody test results. Twenty women who had increased platelet-associated immunoglobulin G levels and positive serum antiplatelet antibody test results were normal 6 to 10 months after delivery. Of 105 infants studied, 10 were thrombocytopenic. Neonatal thrombocytopenia was not predicted by maternal platelet count, platelet-associated immunoglobulin G, or serum antiplatelet antibody. By the fall of 1984, the incidence of thrombocytopenia had dropped to two in 280 consecutive pregnancies. We conclude that (1) epidemics of thrombocytopenia can occur in pregnant women and (2) if a women is found to be thrombocytopenic for the first time during pregnancy, she should not be subjected to the measures advocated for the management of pregnancy in women with autoimmune thrombocytopenic purpura. (Am J Obstet Gynecol 1986;154:878-82.)

During the last 6 months of 1982, a surprisingly large number of asymptomatic women receiving antenatal care at New York University Medical Center were reported to have low platelet counts. At this time the Medical Center introduced new cell-counting machines into the clinical hematology laboratories. These machines provide an unsolicited platelet count on every blood sample submitted. Thus for the first time platelet counts were being reported in asymptomatic pregnant women.

To determine the incidence of thrombocytopenia, we conducted a prospective study of 116 consecutive pregnancies from February, 1983, to September, 1983. We measured platelet-associated immunoglobulin G and tested for the presence of serum antiplatelet antibody in these women. We also obtained platelet counts on their infants to determine if these maternal factors affected the values of the infants.

Methods

The prospective study was conducted from February, 1983, through September, 1983. One hundred sixteen consecutive unselected pregnant women gave informed consent and enrolled in this study during routine prenatal care visits at Bellevue Hospital. Clinical data recorded for all women included age, parity, last menstrual period, gestational age by ultrasound, blood type, and prior medical problems. Complications of pregnancy, labor, delivery, and postpartum course were noted. Platelet counts and antiplatelet antibody studies were performed during at least one prenatal care visit, at the time of admission for delivery, and during the first week post partum. For the purposes of this study, "prenatal" refers to data acquired during a prenatal outpatient visit, up to week 39 of gestation. "Peripartum" refers to data collected from 3 days before delivery through 7 days post partum. Cord serum was collected from 58 deliveries. Birth weight, blood type, gestational age by Dubowitz scoring,[1] and neonatal complications were noted for all infants. Platelet counts were performed on 105 newborn infants.

Blood anticoagulated with ethylenediaminetetraacetic acid was collected for measurement of platelet count and platelet-associated immunoglobulin G. Serum for determination of serum antiplatelet antibody was stored frozen at −20° C until assay, within 1 week. Platelet counts were performed on the day of collection either by an automated cell counter (Coulter Model S-Plus IV, Hialeah, Florida, Ortho Model ELT 800, Raritan, New Jersey) or by the manual technique of Brecker and Cronkite.[2] Low platelet counts were confirmed by review of the peripheral blood smear. Platelet-associated immunoglobulin G and serum antiplatelet antibody were quantitated by solid phase radioimmunoassay as described by Faig and Karpatkin.[3]

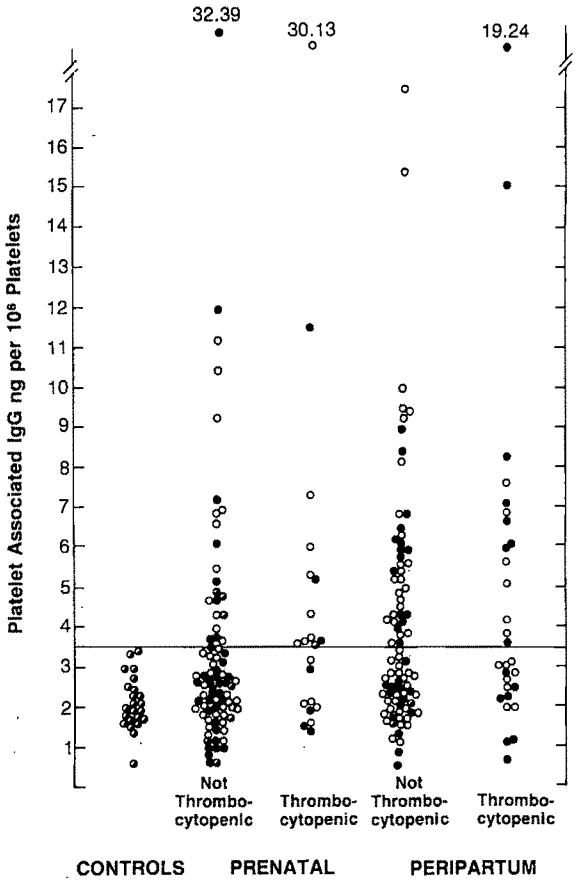

Fig. 1. The level of platelet-associated immunoglobulin G is shown for 23 healthy nonpregnant women, for 28 women who were thrombocytopenic during pregnancy, and for 73 women with uncomplicated pregnancies (not thrombocytopenic, not toxemic, normal infant). Prenatal and peripartum values are given. *Solid circles* indicate that serum antiplatelet antibody results were positive; *open circles* indicate that serum antiplatelet antibody results were negative; *half-filled circles* indicate that serum antiplatelet antibody was not tested. In some women more than one determination was made and results are shown for each determination. Fifty-one percent of determinations in thrombocytopenic women showed increased platelet-associated immunoglobulin G levels and 44% had positive serum antiplatelet antibody results. Seventy-nine percent of thrombocytopenic women had increased platelet-associated immunoglobulin G levels and 61% had positive serum antiplatelet antibody results on at least one occasion. In the nonthrombocytopenic group 36% of platelet-associated immunoglobulin G determinations were positive and 41% had positive serum antiplatelet antibody results. Fifty-nine percent of these women had elevated platelet-associated immunoglobulin G levels on at least one occasion and 59% had at least one positive serum antiplatelet antibody result.

Briefly, in the platelet-associated immunoglobulin G assay, known numbers of washed platelets of a patient are applied to plastic microtiter plates. Adherent platelets are incubated with rabbit antihuman immunoglobulin G. Bound rabbit antiserum is recognized by iodine 125–labeled staphylococcal protein A. Platelet-associ-

ND = Not determined.

ated immunoglobulin G is calculated with reference to pure human immunoglobulin G (Miles Laboratories, Elkhart, Indiana) added directly to the microtiter plates. Samples from 23 healthy nonpregnant women of childbearing age were assayed during the same time period and served as controls for this test. Platelet-associated immunoglobulin G was considered to be positive if the level was >3.46 ng/10^6 platelets, which is the control mean (2.10 ng/10^6 platelets) plus two times the SD (0.68) for nonpregnant women of childbearing age.

In the assay for serum antiplatelet antibody, normal washed platelets are applied to the plastic microtiter plate. Titered patient serum is added to adherent platelets. Bound immunoglobulin G is detected by incubation with ^{125}I-labeled staphylococcal protein A. Serum antiplatelet antibody is considered to be positive if the amount in counts per minute exceeds 1.3 times the counts per minute of pooled control serum in the same assay (>2 SD above the mean).[3]

Statistical analyses were done with Student's *t* test and regression analysis.

Results

In a prospective evaluation of 116 pregnant women, 28 (24%) were noted to be thrombocytopenic at some time during the course of the study. None of these women had a history of autoimmune thrombocytopenic purpura, although one woman had inactive systemic lupus erythematosus not requiring treatment. Nineteen women were thrombocytopenic at a prenatal visit (platelet count 61,000 to 149,000/mm^3) and 13 of these were still thrombocytopenic in the peripartum period. Nine additional women had become thrombocytopenic by the peripartum period (platelet count 43,000 to 149,000/mm^3).

Eighteen of the 28 thrombocytopenic women returned for follow-up platelet counts 3 months to 1 year post partum. One woman, who was pregnant again, had a platelet count of 140,000/mm^3. The other women all had normal platelet counts at follow-up (range 153,000 to 435,000/mm^3).

Fig. 1 shows the results of antiplatelet antibody studies in 23 nonpregnant women of childbearing age, in the 28 women who were thrombocytopenic, and in 73 women with normal platelet counts and uncomplicated pregnancies. Each point represents the level of platelet-associated immunoglobulin G as shown on the y axis. *Open circles* indicate that test results for serum antiplatelet antibody were negative; *closed circles,* that results were positive; and *half-filled circles,* that serum antiplatelet antibody was not measured. Some of the pregnant women were tested on more than one occasion. Seventy-nine percent of these thrombocytopenic women had increased platelet-associated immunoglobulin G levels and 61% had positive results for serum antiplatelet antibody on at least one occasion. There was no correlation between increased platelet-associated immunoglobulin G levels and positive results of serum antiplatelet antibody. Of the nonthrombocytopenic women, 59% had elevated platelet-associated immunoglobulin G levels on at least on occasion, and 59% had at least one positive test result for serum antiplatelet antibody.

The mean values and range were not different from those in the thrombocytopenic women. As in the thrombocytopenic women, the platelet-associated immunoglobulin G level did not correlate with the presence of serum antiplatelet antibody. Postpartum levels of platelet-associated immunoglobulin G were significantly higher than third-trimester values (4.04 ± 0.41 versus 2.94 ± 0.23 ng/10^6 platelets, mean ± SEM, 60 pairs, $p < 0.02$). Parity had no effect on antiplatelet antibody levels, nor did a blood group incompatibility between mother and fetus.

Fifteen women became toxemic during pregnancy. Six were thrombocytopenic. The proportions of elevated platelet-associated immunoglobulin G levels and positive serum antiplatelet antibody results were similar to those observed in thrombocytopenic women without toxemia as well as in women with normal platelet counts.

Twenty women who had increased platelet-associated immunoglobulin G levels (12) and/or positive serum antiplatelet antibody results (nine) were studied 6 to 10 months after delivery. Thirteen had been thrombocytopenic during pregnancy. All had platelet-associated immunoglobulin G levels of <3.46 ng/10^6 platelets, negative serum antiplatelet antibody results, and normal platelet counts.

Platelet counts were done for 105 neonates whose mothers were enrolled in the study. Ten infants became thrombocytopenic by 5 days of age. Clinical and laboratory data for these infants are shown in Table I. Six thrombocytopenic infants had neonatal complications that could be associated with thrombocytopenia; however, these infants were included since it was not known if immune factors played a role in causing thrombocytopenia. Maternal platlet count, platelet-associated immunoglobulin G levels, and serum antiplatelet antibody results were not predictive of neonatal thrombocytopenia (Table II). Among 68 women who had elevated platelet-associated immunoglobulin G levels on at least one occasion, only four gave birth to a thrombocytopenic infant. Of 37 women in whom platelet-associated immunoglobulin G levels were never elevated, six gave birth to a thrombocytopenic infant. Of 64 women with positive serum antiplatelet antibody results, seven had thrombocytopenic offspring. Three of 41 women with consistently negative serum antiplatelet antibody results had thrombocytopenic infants.

Cord serum antiplatelet antibody results were positive in only four of 58 samples tested (6.9%). These four infants were not thrombocytopenic (platelet count 150,000 to 334,000/mm³), although one of the four mothers was thrombocytopenic, with a platelet count of 95,000/mm³.

After the study had been completed and while the article was in preparation it was noted that the hematology staff were being consulted less frequently about pregnant women with low platelet counts. Therefore the routine laboratory data on 200 consecutive women who attended the prenatal clinic during the fall of 1984 were examined. Only two had a platelet count <150,000/mm³.

Table II. The incidence of neonatal thrombocytopenia among 105 infants with regard to maternal factors

Maternal factor	*No.*	*Thrombocytopenic infants*	
		n	%
Thrombocytopenic	26	3	12
Nonthrombocytopenic	79	7	9
Positive platelet-associated immunoglobulin G	68	4	6
Negative platelet-associated immunoglobulin G	37	6	16
Positive serum antiplatelet antibody	64	7	11
Negative serum antiplatelet antibody	41	3	7

Comment

Twenty-eight of 116 healthy pregnant women seen at this Medical Center in an 8-month period in 1983 had a low platelet count at least once during pregnancy. Published studies of platelet counts during normal pregnancy do not report such a high incidence of thrombocytopenia, and this is also true of our own more recent experience. However, review of the literature does reveal that platelet counts below the normal range do occur in uncomplicatd pregnancy. In 1948 Ward and MacArthur[4] performed platelet counts for 200 healthy women each month from the second month of pregnancy until term. They published the minimum and maximum counts for each month. In every month there were counts of <150,000/mm³ and the minimum counts ranged from 54,000/mm³ (eighth month) to 85,000/mm³ (fifth month).[4] In 1956, Fresh et al.[5] performed platelet counts at the time of delivery in 32 normal pregnancies and reported counts as low as 105,000/mm³. Bonnar and McNicol,[6] in 1969, carried out multiple counts for 10 women between 12 weeks of pregnancy and term and recorded seven counts of <150,000/mm³. Sejeny et al.[7] studied 405 normal women during pregnancy. They reported a significant progressive fall in platelet count during the course of the pregnancy and commented that the lowest counts in some women were outside the normal range. The lowest count recorded was 75,000/mm³.

In 1982, Kelton et al.[8] published a study of 41 pregnancies in 38 patients clinically diagnosed as having immune thrombocytopenia. Out of 23 patients avail-

able for follow-up, the platelet count returned to normal in 11 without therapy after delivery. One may speculate that these 11 patients did not have classic autoimmune thrombocytopenia, but as in our patients the thrombocytopenia was a pregnancy-related phenomenon. Only one half of the thrombocytopenic mothers studied by Kelton et al. had elevated platelet-associated immunoglobulin G levels, similar to our finding of 59%. This is in contrast to the usual finding in patients with autoimmune thrombocytopenia where approximately 90% have elevated platelet-associated immunoglobulin G levels.[3]

It is of interest that the incidence of low platelet counts fell dramatically within a year of completion of the study. One possible explanation for this apparently limited "epidemic" of thrombocytopenia in pregnancy is that the counts were not really low but were an artifact produced by the cell counters. This explanation can be discounted because each time a low platelet count was recorded, a stained blood smear was examined by an experienced observer in order to confirm the accuracy of the count. In addition, of the 19 women who were found to be thrombocytopenic in the prenatal period, 13 were still thrombocytopenic perinatally, making the possibility of a machine error extremely unlikely.

A possible explanation is that the thrombocytopenia was a response to a virus that was prevalent in the community during the period of the study and subsequently disappeared. Viral infections are known to cause transient thrombocytopenia, frequently accompanied by the deposition of immune complexes on platelets.[9] The question that then arises is why was this phenomenon observed only in pregnant women? Possible explanations are: (1) that the pregnant state made the women more susceptible to the hypothetical virus, (2) that platelets become altered during the pregnant state, causing immune complexes to bind to them more readily, or (3) that thrombocytopenia was in fact occurring in healthy people who were not pregnant but this occurrence was not noticed because platelet counts were not performed for these people. This latter explanation is unlikely because a platelet count is obtained for healthy people entering the hospital for routine surgical procedures and no such epidemic of thrombocytopenia was noted among this group of patients during the time this study was carried out. Masson et al.[10] reported immune complexes in the sera of all of 55 healthy pregnant women studied, although others[11,12] have been unable to confirm this. It is possible that the combination of a viral infection and the pregnant state resulted in formation of immune complexes, which in some women bound to the platelets.

Not all women with immunoglobulin G demonstrable on the platelets were thrombocytopenic. This is not surprising because recent studies in nonthrombocytopenic homosexual men and intravenous drug abusers at risk for acquired immune deficiency syndrome, who have been exposed to human T-lymphotropic virus type III, show that they have immunoglobulin G–containing circulating immune complexes with markedly elevated immunoglobulin G on the platelets, suggesting the deposition of immune complexes.[13,14] The incidence of thrombocytopenia in these patients may reflect other influences such as activity of the reticuloendothelial system and the ability of the bone marrow to compensate for shortened platelet life span.

One reason for undertaking this study was to identify any relationship between maternal platelet count, platelet-associated immunoglobulin G, and serum antiplatelet antibody and the platelet count in the neonate. No relationship was demonstrated. Ten infants were thrombocytopenic in the neonatal period (Table I) but maternal platelet count, platelet-associated immunoglobulin G, and serum antiplatelet antibody were not predictive of thrombocytopenia. Indeed six of these infants had other reasons for thrombocytopenia, including sepsis.

As a result of this study we suggest that if a woman is found to be thrombocytopenic for the first time during pregnancy it should not automatically be assumed that she had autoimmune thrombocytopenic purpura and she should not be subjected to the measures usually advocated for management of pregnancy in a woman with autoimmune thrombocytopenic purpura.[15-17] Indeed one woman had a platelet count of 49,000/mm^3, but her child was not thrombocytopenic. Platelet antibody studies will not be helpful in identifying women who have autoimmune thrombocytopenia. If the index of suspicion is high for autoimmune disease (history of long-term bleeding tendency, history of other autoimmune disease), these women may be treated as for autoimmune thrombocytopenic purpura, and their pregnancies managed accordingly. If the diagnosis of autoimmune thrombocytopenic purpura cannot be made, it would seem that the infants may be safely delivered vaginally without the necessity for maternal steroid therapy or fetal scalp platelet count.

Longitudinal study of platelet indices during normal pregnancy

Steven G. Tygart, M.D., Dennis K. McRoyan, M.D., Joseph A. Spinnato, M.D., Cheryl J. McRoyan, M.T.(A.S.C.P.)S.H., and David Z. Kitay, M.D.

Mobile, Alabama

The purpose of this longitudinal, prospective study was to define platelet indices during normal pregnancy and to compare them to normal nonpregnant values. Indices evaluated included platelet count, mean platelet volume, and platelet distribution width. No significant change occurred in the mean platelet count or mean platelet volume from the second to the third trimester; however, platelet distribution width increased progressively and significantly during this interval ($p < 0.0001$). Mean platelet volume versus platelet count showed a significant inverse relationship ($p < 0.0001$) and was congruent with normal nonpregnant values. Mean platelet volume versus platelet distribution width exhibited a significant direct relationship ($p < 0.03$) that differed remarkably from normal nonpregnant values. These data support the concept of normal pregnancy as a compensated state of progressive platelet consumption. These findings may have important diagnostic and prognostic applications in discerning acute states of platelet consumption superimposed on the compensated consumption of normal pregnancy. (AM J OBSTET GYNECOL 1986;154:883-7.)

Key words: Platelet count, mean platelet volume, platelet distribution width, thrombocytopoiesis, preeclampsia

Prior to the introduction of automated hematology analyzers, 11 studies of platelet count during normal pregnancy reported either an increase, a decrease, or no change with gestation.[1, 2] Since the advent of automated instruments, there have been eight reports of platelet count during pregnancy.[3-7] Three of these studies were longitudinal in design and reported no significant difference in the mean platelet count between the second and third trimesters.[5-7]

Additionally, automation facilitated the evaluation of mean platelet volume and platelet distribution width in health and disease.[8, 9] These indices have been shown to reflect bone marrow thrombocytopoietic activity that precedes changes in the platelet count. Fay et al.[4] have recently investigated platelet count, mean platelet volume, and platelet distribution width in a cross-sectional study and interpreted their data to suggest platelet "hyperdestruction" throughout normal pregnancy. In our study, these platelet indices are evaluated longitudinally in uncomplicated pregnancy.

Material and methods

The study population consisted of 51 pregnant women ranging in age from 15 to 32 years who at-

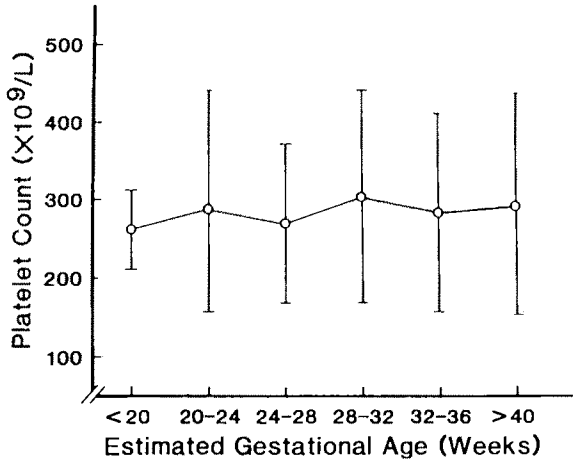

Fig. 1. Platelet count in normal pregnancy (mean ± 2 SD).

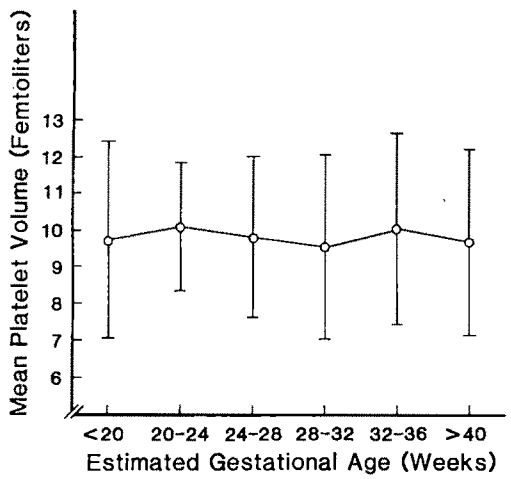

Fig. 2. Mean platelet volume in normal pregnancy (mean ± 2SD).

tended the antenatal clinics of the University of South Alabama Medical Center. Racial distribution was 60% black and 40% white. Blood samples were obtained from those routinely collected for the purpose of quantifying hemoglobin; no additional blood was required for our study. An aliquot of blood obtained by antecubital venipuncture into Vacutainer blood-collecting tubes containing disodium ethylenediaminetetra-acetic acid was analyzed 2 to 24 hours following collection with the use of a Coulter Counter Model S Plus II (Coulter Electronics, Inc., Hialeah, Florida) that was subjected to daily quality control. Platelet count, mean platelet volume, and platelet distribution width were generated synchronously with complete blood count. The mean platelet volume, measured in femtoliters, is defined as the aggregate volume of platelets divided by the platelet count; platelet distribution width is an index of the range of the volume distribution of the platelet population mathematically extrapolated for best fit.[8]

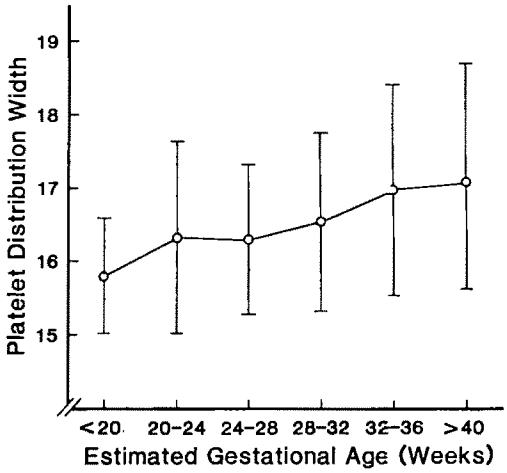

Fig. 3. Platelet distribution width in normal pregnancy (mean ± 2 SD). Groups differ significantly with gestation ($p < 0.0001$).

The platelet distribution width has not been released for clinical use.

Specimens were collected serially, coincident with clinic visits, between 20 and 43 weeks' estimated gestational age. The estimated gestational age was estimated clinically and/or ultrasonographically. All patients received oral iron supplements (ferrous sulfate, 65 mg daily) and maintained a hemoglobin level above 10 gm/dl. Pregnancies complicated by hypertensive disorders were excluded. Samples obtained from laboring patients were also excluded from this analysis.

The following relationships were statistically analyzed as the mean ± 2 SD (platelet count vs. estimated gestational age, mean platelet volume vs. estimated gestational age, platelet distribution width vs. estimated gestational age) or by the linear regression model for best least squares fit ±2 SD of the overall mean (mean platelet volume vs. platelet count, mean platelet volume vs. platelet distribution width). The level of statistical significance was set at 0.05. For descriptive and comparative purposes, data presented in Figs. 1 to 3 are grouped into 4-week intervals and the mean ± 2 SD of these intervals is graphically displayed. Nomograms were constructed and compared with published ranges for normal nonpregnant individuals generated on comparable instruments with the use of the manufacturer's controls.[10, 11]

Results

One hundred ninety-two samples were collected from 51 patients. From this total, 31 observations were excluded from the group analysis. Thirteen samples were obtained from patients who were in labor or who developed preeclampsia. An additional 18 samples were excluded because they did not represent longi-

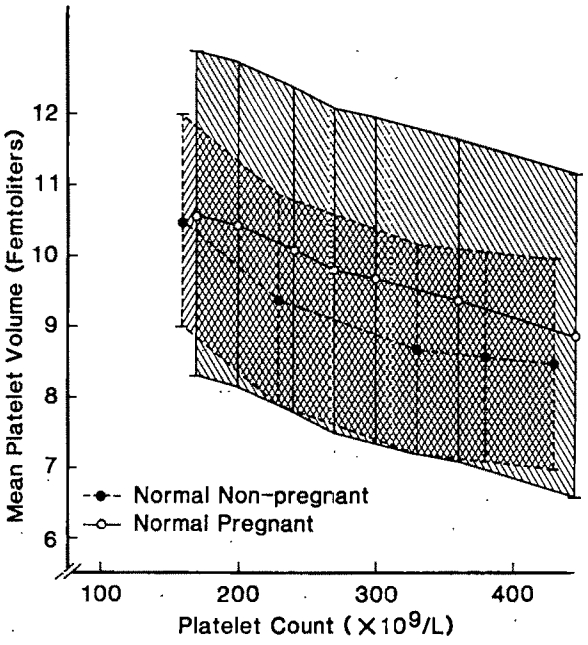

Fig. 4. Mean platelet volume versus platelet count in normal pregnancy *(solid line)* (best least squares model ±2 SD overall mean) exhibiting a significant inverse relationship ($p < 0.0001$). The inverse relationship of platelet size and count in normal subjects, and an artifact of other particles. Am J Clin Pathol 1981;76:289.)

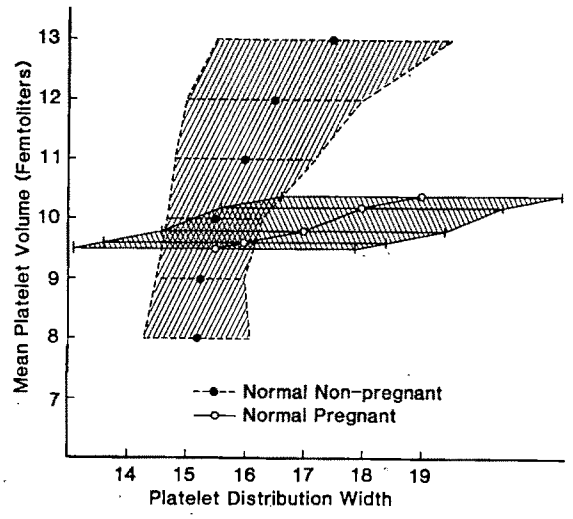

Fig. 5. Mean platelet volume versus platelet distribution width in normal pregnancy *(solid line)* (best least squares model ±2 SD of overall mean) exhibiting a significant direct relationship ($p < 0.03$). Mean platelet volume versus platelet distribution width in normal nonpregnant population *(dashed line)* (mean ± 2 SD). (Used with permission from Bessman JD, Williams LJ, Gilmer PR. Platelet size in health and hematologic disease. Am J Clin Pathol 1982;78:150.)

tudinal observations. The remaining 161 samples from 41 patients were analyzed.

Fig. 1 illustrates the relationship of platelet count versus estimated gestational age. Fig. 2 demonstrates mean platelet volume versus estimated gestational age. Significant change across the second and third trimesters could not be demonstrated. The mean platelet volume ranged from 7.0 to 13.1 fl.

Fig. 3 illustrates platelet distribution width versus estimated gestational age. Platelet distribution width increased progressively with advancing estimated gestational age ($r = 0.53$; $p < 0.0001$). Platelet distribution width ranged from 15 to 19.

Fig. 4 illustrates the mean platelet volume versus platelet count and compares this range with the reference range for a normal nonpregnant population (data expressed as mean ± 2 SD[9, 10]). A significant inverse relationship was identified ($r = -0.34$; $p < 0.03$), and it was congruent with the reference range.

Fig. 5 illustrates the relationship of mean platelet volume versus platelet distribution width and compares this range with the reference range for a normal nonpregnant population (data expressed as mean ± 2 SD[11]). A significant direct relationship ($r = 0.19$; $p < 0.03$) was identified, and it differed remarkably from the reference range.

Comment

The data indicate that the mean platelet count does not differ significantly from the second to third trimester, which is consistent with other longitudinal studies during this interval. Although the mean platelet volume did not differ significantly, a highly significant increase in platelet distribution width was discerned during this interval. The findings of this study are in partial agreement with the cross-sectional data of Fay et al.,[4] which demonstrate a significant decrease in platelet count and an increase in mean platelet volume and platelet distribution width with gestational age. These authors interpreted their data to indicate platelet "hyperdestruction" throughout normal pregnancy. Since the mean platelet count did not change significantly, we interpret our data to indicate a compensated state of progressive platelet consumption during normal pregnancy. Numerous investigations support the concept of normal pregnancy as a compensated state of subclinical coagulopathy and suggest maintenance of the uteroplacental interface as its focus. Among the most recent, Rakoczi et al.[12] demonstrated in a limited sampling that platelet half-life appears shorter in pregnancy in comparison with nonpregnant control subjects. β-Thromboglobulin, a platelet-specific release

protein, was found by Douglas et al.[13] to be significantly elevated during the second and third trimesters in comparison with first-trimester values, the values of patients taking oral contraceptives, and the values of nonpregnant control subjects. Further, measurements of soluble fibrin complexes, which are increased in thrombosis and disseminated intravascular coagulation, were found to be significantly increased by the second gestational month and to increase steadily to five times control values by term.[14]

The relationship of mean platelet volume to platelet count was congruent with Bessman's nomogram[9, 10] for normal nonpregnant populations; however, our mean was elevated. The relationship of mean platelet volume to platelet distribution width differed remarkably from Bessman's nomogram[10] for nonpregnant individuals but is not conceptually inconsistent with it. Our data suggest an elevated level of thrombocytopoiesis, which is consistent with a compensated state of progressive platelet consumption that differs from that in the normal population observed by Bessman only by the degree of thrombocytopoiesis implied. This conclusion is based on extrapolations of current concepts of platelet volume behavior in health and disease.[9-11] Bessman and others have demonstrated the following: (1) The mean platelet volume remains unchanged to mildly elevated in compensated states of platelet consumption, that is, chronic immune thrombocytopenia; (2) in severe uncompensated states of platelet consumption, that is, acute immune thrombocytopenia and disseminated intravascular coagulation, mean platelet volume increases markedly and proportionately with the demand for platelet production; (3) in conditions stimulating thrombocytopoiesis, increases in platelet distribution width would be expected to accelerate when mean platelet volume increases because increasing stimulation to platelet production broadens the distribution of platelet sizes produced and affects the platelet distribution width more than the mean platelet volume. Our data demonstrate a mildly elevated mean platelet volume and a greater unit increase in platelet distribution width versus mean platelet volume in comparison with Bessman's nomograms[10, 11] (Figs. 4 and 5). We interpret these data to represent an increased level of thrombocytopoiesis, which is the result of both the dilutional and the consumptive stimuli of normal pregnancy.

These findings may contribute to the understanding of the pathophysiology of thrombocytopenia in preeclampsia. In comparison with normal pregnant control subjects, patients with preeclampsia exhibit a statistically significant decrease in platelet half-life, as well as increases in plasma levels of β-thromboglobulin and soluble fibrin monomers.[12-14] Additionally, platelet consumption has been shown to be an early feature of preeclampsia, which in approximately 20% of patients with severe preeclampsia results in thrombocytopenia, the most common hemostatic abnormality observed in patients with preeclampsia.[15] Further, Giles and Inglis[16] have shown that the platelet count is significantly lower and the mean platelet volume significantly higher in patients with preeclampsia in comparison with normal control subjects or in nonpreeclamptic patients with hypertension. Taken together, these observations suggest that preeclampsia may be associated with an acute coagulopathic state that precedes the clinical onset of disease. Since changes in mean platelet volume and platelet distribution width may precede changes in platelet count and may reflect alterations in the bone marrow environment even in the absence of significant changes in the peripheral platelet count, i.e., compensated states, we suggest that these indices may have both diagnostic and prognostic value in gestational hypertensive states. The occurrence of accelerated platelet consumption in preeclampsia, coupled with low cost and availability of quantification of mean platelet volume and platelet distribution width on automated instruments (with Food and Drug Administration approval), may justify antenatal screening.

In summary, platelet distribution width, mean platelet volume, and platelet count and their interrelationships have now been evaluated longitudinally in pregnancy. These baseline data suggest that uncomplicated pregnancy results in a chronic, progressive state of platelet turnover. Since preeclampsia may be associated with platelet consumption beyond normal gestational demands, we suggest that quantification of platelet indices may have value in screening for and following this disorder. A prospective study is being designed to expand the data base and to apply it to the investigation of gestational hypertension.

Aortic function during normal human pregnancy

Mark V. Hart, M.S., Mark J. Morton, M.D., Jeffrey D. Hosenpud, M.D., and James Metcalfe, M.D.
Portland, Oregon

Arterial rupture and dissection have been observed in both normal and complicated pregnancies. To understand how arterial mechanical properties might change during pregnancy, we measured aortic root diameter by M-mode echocardiography and obtained simultaneous cuff blood pressures during systole and diastole at rest and during isometric exercise. Measurements were obtained in 19 women at the end of normal gestation and again 3 to 6 months post partum. The aorta is larger and more compliant during normal human pregnancy, and these changes may not revert to prepregnant levels post partum. Increased aortic compliance, combined with decreased vascular resistance, may enhance left ventricular performance in normal pregnancy. Conversely, the presumed structural alterations leading to increased compliance may weaken diseased vessels leading to dissection or rupture during pregnancy. (AM J OBSTET GYNECOL 1986;154:887-91.)

Key words: Pregnancy, aortic compliance, aortic size

Rupture of the aorta or one of its branches is an important but infrequent source of maternal morbidity and mortality.[1] While coarctation and Marfan's syndrome[2] are common predisposing factors to these catastrophes, many pregnant women have no apparent cause for arterial rupture. The assessment of maternal aortic structure and function is therefore an important topic. However, information is meager and conflicting regarding whether aortic structure, assessed by light microscopy, is altered during pregnancy.[3, 4]

Even less information is available regarding aortic function during pregnancy. Arterial diastolic pressure declines during pregnancy, a change which should be associated with decreased aortic diameter. However, an echocardiographic study of women throughout pregnancy demonstrated a consistent increase in aortic diastolic diameter during gestation while diastolic blood pressure decreased.[5] Although significant differences were not noted, the data were suggestive of a change in aortic pressure-dimension relationship during pregnancy. However, the stress-strain relationship of rabbit aortic strips in vitro was not affected by pregnancy.[6]

A shift of the aortic pressure-dimension relation would suggest pregnancy-related changes in aortic function and structure and a mechanism for the apparent aortic fragility during gestation. Great vessel mechanics also significantly affect ventricular function.[7] If present, increased aortic compliance would reduce ventricular afterload and enhance left ventricular performance. The goal of the present study was to estimate aortic pressure-dimension relations during and after pregnancy. Measurements were made at several aortic pressures in order to avoid possibly confounding spontaneous pressure changes.

Methods

Subject selection. Study subjects were recruited from consecutive admissions to the Labor and Delivery Service of the Oregon Health Sciences University Hospital. Patients were excluded from the study for any of the following reasons: history of cardiovascular disease, medical complications during pregnancy, multiple pregnancy, advanced stage of labor, or refusal or

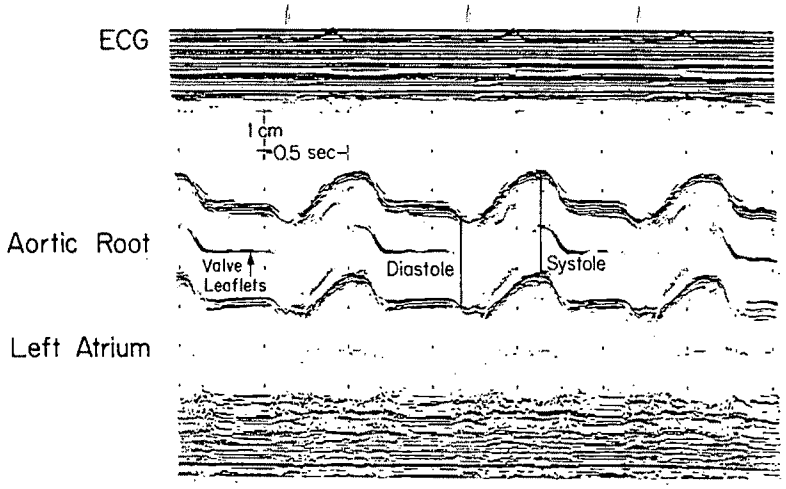

Fig. 1. M-mode echocardiographic display of the aorta during three consecutive cardiac cycles. The aortic valve leaflets are clearly visualized when closed during diastole in the middle of the aortic root, thus providing a consistent landmark for subsequent measurements.

Table I. Maternal and fetal demographic characteristics

	All	*Primiparous* ($n = 7$)	*Multiparous* ($n = 12$)
Fetal weight (gm)	3708 ± 456	3628 ± 567	3810 ± 413
Prepregnant body (m^2)	1.62 ± 0.13	1.68 ± 0.14	1.59 ± 0.12
Gestational weight (kg)	76 ± 12	81 ± 13	73 ± 11
Maternal age (yr)	25 ± 6	23 ± 8	26 ± 5
Gestational age (wk)	40 ± 2	40 ± 2	40 ± 1
Time of postpartum study (wk)	15 ± 7	13 ± 6	16 ± 8
Lactating	10/19	3/7	7/12

inability of the subject to return for a postpartum examination. No subjects were taking medications with cardiovascular activity. After written informed consent, all subjects underwent identical study protocols at the end of gestation and again 3 to 6 months post partum. This investigational protocol was reviewed and approved by the institutional committee on human research.

Study protocol. After resting in the left lateral recumbent position for 10 minutes, M-mode echocardiograms and electrocardiograms were recorded with a Smith-Kline Echoline 20A ultrasonoscope and a strip recorder as previously described.[8] No measurements were made during uterine contractions. Blood pressures were measured simultaneously by sphygmomanometer and auscultation. A 2.25 MHz transducer was positioned in the third or fourth intercostal space to obtain left ventricular measurements. The transducer was then angled superiorly and medially in order to visualize the aortic root in a plane that intersected the aortic valve leaflets during diastole (Fig. 1). Aortic measurements were determined by means of the leading edge technique from the average of five cycles during end diastole (onset of QRS) and end systole (aortic valve closure).[9] In order to provide aortic measurements over a range of pressures, subjects performed isometric exercise with a hand dynanometer and aortic dimensions and blood pressures were obtained at 1-minute intervals until the subjects ceased exercise because of fatigue (3 to 5 minutes at 50% maximum strength).

In order to assess aortic compliance, aortic cross-sectional area (A) was calculated from each measured dimension (D), assuming the aorta to be a cylinder with a length indifferent to pressure ($A = \pi D^2/4$). Cross-sectional area was normalized for prepregnant body surface area in order to account for individual variability related to body size, independent of pregnancy.

The relationships between aortic pressure and cross-sectional area were analyzed by analysis of covariance to determine pregnancy-related changes in slope and cross-sectional area. The reduced data are presented as slopes and y-adjusted means. All other hemodynamic and echocardiographic data were analyzed by paired t test for comparisons between pregnant and post partum states. Demographic data were tested by unpaired t test.

Results

The study group consisted of 19 women who were 15 to 35 years of age (mean = 25) and who had normal

Table II. Resting hemodynamic and echocardiographic data during pregnancy and postpartum period

	End gestation			*Postpartum period*		
	All	*Primiparous (n = 7)*	*Multiparous (n = 12)*	*All*	*Primiparous (n = 7)*	*Multiparous (n = 12)*
Heart rate (beats · min^{-1})	80 ± 14*	72 ± 9†	85 ± 14*	67 ± 9	63 ± 7	69 ± 8
Systolic blood pressure (mm Hg)	115 ± 11	118 ± 11	114 ±	107 ± 8	105 ± 6	109 ± 9
Diastolic blood pressure (mm Hg)	70 ± 10	71 ± 7	69 ± 12	70 ± 7	70 ± 6	70 ± 8

term pregnancies. Seven of the women were primiparous and 12 multiparous (Table I). Table II depicts hemodynamic and echocardiographic data at end gestation and late post partum. Heart rate, normalized mean aortic root area, and compliance were all greater at end gestation than post partum.

A plot of aortic pressures both at rest and during exercise versus aortic cross-sectional area is shown in Fig. 2. The correlation coefficients for the pregnant and postpartum groups are $r = 0.44$ ($p < 0.01$) and $r = 0.67$ ($p < 0.001$), respectively. Analysis of covariance shows that the slope of the aortic pressure-area relation of subjects in late gestation is significantly less ($p < 0.005$) than that of the same women post partum (Table II). Since this regression coefficient (slope) is the inverse of compliance, we interpret these data to mean that the aortic root is more compliant during the third trimester of pregnancy than post partum.

The effect of parity on aortic size and compliance is shown in Fig. 3, *A* and *B*. There was a significant difference in mean aortic cross-sectional area (analysis of covariance) between multiparous and primiparous women, both during pregnancy (4.94 ± 1.31 versus 3.78 ± 0.75 cm^2/m^2, $p < 0.001$, respectively) and post partum (3.63 ± 0.78 versus 3.26 ± 0.63, $p < 0.025$, respectively). Aortic compliance was significantly greater in multiparous than primiparous women during late gestation; however, compliance was not different between the two groups post partum.

Comment

M-mode echocardiography provided a technique for assessing aortic pressure-dimension relationships during human pregnancy that was safe and acceptable to volunteers. Furthermore, M-mode measurements of the human aortic root accurately reflect angiographically determined dimensions over a wide range of aortic size.[10] The timing and amplitude of brachial arterial pressures determined by auscultation differ from those in the ascending aorta, but the differences are not of sufficient magnitude to influence the conclusions of this study. It is important to note that we measured aortic dimension at end systole and not at the time of peak systolic pressure. Our primary concern was that an accurate and reproducible measurement of systolic aortic diameter be obtained. Inspection of Greenfield and Patel's direct measurements of human aortic pressure-dimension relations[11] shows that aortic dimension changes insignificantly between maximum excursion and aortic valve closure. Last, estimates of aortic diameter by echocardiogram would be falsely increased if images were obtained more tangentially during pregnancy because of changes in position of the heart and great vessels. The frontal electrical axis shifts about 15 degrees to the left during pregnancy but little is known about the position of the heart or great vessels.[12] In our experience, the aorta is not well visualized with M mode when viewed tangentially. Finally, an angle greater than 30 degrees from perpendicular would be necessary to explain our results during pregnancy. For all of these reasons, we believe that our pressure-dimension measurements of the aorta give an accurate assessment of aortic size and compliance.

In an earlier serial echocardiographic study, Katz et al.[5] measured several parameters during pregnancy, including aortic root diameter and blood pressure. They found a significant decrease in diastolic blood pressure during the third trimester when compared with postpartum values; a nonsignificant increase in aortic root diameter was observed during the second and third trimesters compared with postpartum values. Our data confirm this trend of increasing aortic diameter during pregnancy, but we did not find a decreased diastolic blood pressure at end gestation. Other observers have noted that diastolic pressure falls in the second trimester and returns to postpartum values in the third trimester.[13] Our data, therefore are entirely compatible with those of Katz et al.[5] However, because

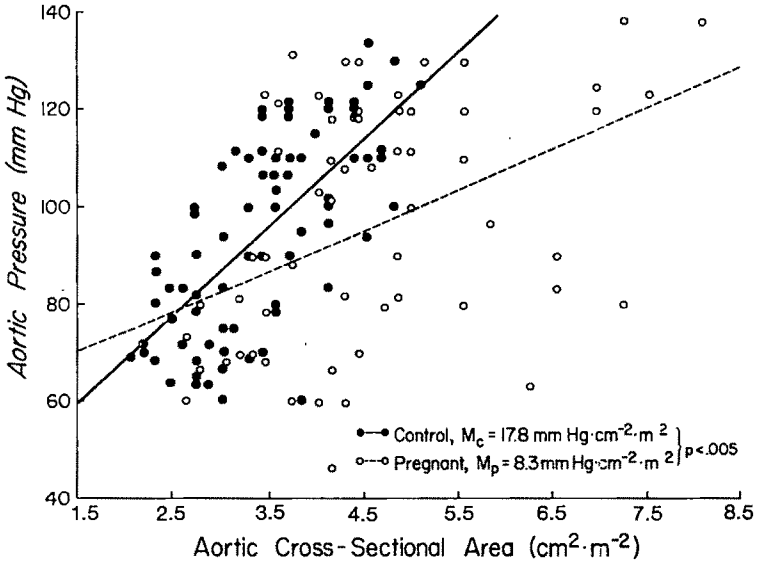

Fig. 2. Aortic pressure–cross-sectional area relationship during pregnancy and post partum. The slope (inverse of compliance) is less during pregnancy, indicating that compliance is greater during this period.

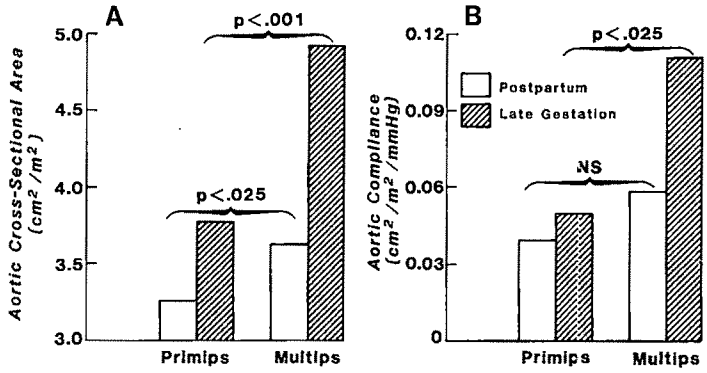

Fig. 3. The effect of parity on aortic cross-sectional area *(A)* and aortic compliance *(B)*. Compared with primiparous women, multiparous women had larger and more compliant aortas during pregnancy. By 3 months post partum, the aortas of multiparous women were still larger than those of primiparous women, but compliance was not different. Aortic cross-sectional area and compliance were greater during pregnancy than post partum for both groups (see Table II).

we examined the aortic pressure-dimension relationship in each subject at several pressures, we are able to offer conclusions regarding the effect of pregnancy on aortic function.

This study was not designed to elicit the underlying mechanism by which aortic mechanical properties are altered during normal pregnancy, but several factors may be involved and are worthy of consideration. Material property changes of the aorta could account for our findings during pregnancy, but only conflicting data concerning the cellular alterations seen in aortic walls during pregnancy are available.[3, 4] Blood volume is increased 40% at term in normal human pregnancy and acute volume loading in dogs increases aortic dimension and compliance.[14] The effect of volume loading on aortic function was noted to be independent of autonomic tone and arterial pressure. However, α-adrenergic tone also affects aortic function.[15] Reduced adrenergic tone in pregnancy has been suggested, but we are unaware of studies that have assessed adrenergic stimulation of aortic smooth muscle during pregnancy.

It appears that sex steroids may play a prominent role in aortic alterations during pregnancy through both direct and indirect effects. It has been noted that several species, including primates, possess specific high-affinity receptor sites for estrogen in aortic tissue.[16] Beldekas et al.[17] have demonstrated that estradiol alters the biosynthesis of collagen in aortic smooth muscle cells by decreasing collagen production and altering the ratio of type I to type II procollagen fractions. Estrogen may also be partly responsible for the large increase in blood volume during pregnancy and blood

volume may affect aortic function as discussed previously. Finally, recent studies have shown that estradiol stimulates the production of prostaglandin cyclooxygenase and prostacyclin synthetase in aortic smooth muscle cells.[18] This is of particular interest as Paller[19] has demonstrated a decreased pressor response to angiotensin II, norepinephrine, and vasopressin during pregnancy in rats. He showed that the blunted pressor response was not due to a change in affinity or number of smooth muscle receptors and that this response could be reversed by administration of a prostaglandin synthesis inhibitor. These observations suggest that the blunted pressor response during pregnancy is mediated by an estrogen-induced increase in prostaglandin synthesis.

We found that multiparous women had larger aortas than primiparous women both during pregnancy and post partum, but aortic compliance was not different between the two groups post partum. These data suggest that some of the alterations of aortic pressure-dimension relations do not revert to the prepregnant state after delivery or return more slowly in multiparous women than in primiparous women.

Increased aortic compliance importantly affects ventricular function. During normal pregnancy in humans and guinea pigs, the left ventricle enlarges in association with an increased stroke volume.[5, 20] However, the ratio of left ventricular radius to wall thickness is increased, a change that would increase wall stress and afterload if aortic impedance were unchanged. The reduced vascular resistance that occurs in pregnancy, combined with the increased aortic compliance reported here, reduces impedance in normal human pregnancy and may explain the preservation of left ventricular shortening velocity noted by Katz et al.[5]

Our findings suggest that aortic structure is altered during human pregnancy and that structural changes explain both the increased aortic dimension and compliance and the unfortunate tendency for aortic fragility during pregnancy. Definitive studies regarding this hypothesis are not available. Biochemical and functional changes in the uterine arteries during pregnancy are well documented and sex steroids, especially estrogen, may play an important role in these changes.[21] These studies need to be extended to the aorta and the role of sex steroids in this process needs to be determined.

We express our gratitude to Dr. J.-C. Veille, Marilyn Paul, and the Labor and Delivery staff of the Oregon Health Sciences University Hospital for their assistance in patient recruitment.

Correlation of the ultrasonic appearance of the ovaries in polycystic ovarian disease and the clinical, hormonal, and laparoscopic findings

Gamal H. el Tabbakh, M.D., Ibrahim Lotfy, M.D., Ibrahim Azab, M.D., Hany A. Rahman, M.D., Aaron L. Southren, M.D., and Fatma A. Aleem, M.D., Ph.D.
Alexandria, Egypt, and Valhalla, New York

The ovarian ultrasonic appearance in 20 patients with polycystic ovarian disease was studied and correlated to the clinical, hormonal, and laparoscopic findings. Ultrasound studies showec that both ovaries were enlarged in 15 patients (15.46 ± 2.5 cm^3). Maximum ovarian surface area was 9.75 ± 3.38 cm^2. Three ultrasonic patterns were detected: (1) isoechoic, with no discernible cysts (four patients); (2) hypoechoic, with multiple small cysts of <1 cm (11 patients); (3) hypoechoic, with single cyst of >1 cm (five patients). Ultrasonic estimation of ovarian size was superior to clinical assessment and equal to that of laparoscopic examination. Subtle differences existed between the ultrasonic appearance of the ovaries in hyperprolactinemic subgroups of polycystic ovarian disease compared to normoprolactinemic ones. However, no significant relationship was found between the ovarian size and any of the hormones studied. Obesity, amenorrhea, hirsutism, hyperprolactinemia, and elevated testosterone and dehydroepiandrosterone sulfate levels were more common in the group with enlarged ovaries, whereas oligomenorrhea, elevated luteinizing hormone/follicle-stimulating hormone ratio, and elevated androstenedione and estrone levels occurred more frequently in the group with normal-sized ovaries. The value of ultrasound studies in the management of polycystic ovarian disease is emphasized. (Am J Obstet Gynecol 1986;154:892-5.)

Key words: Ultrasound, polycystic ovaries, prolactin

Polycystic ovarian disease presents a spectrum of overlapping ovarian and adrenal abnormalities with variable clinical manifestations. The diagnosis of polycystic ovarian disease is sometimes elusive and requires visualization of both ovaries. The first ultrasonic observation of enlarged ovaries in patients with the disease were those of Kratochwil et al.[1] and Zemlyn.[2]

Several reports[3-6] have recently appeared on the sonographic morphology of polycystic ovaries. The ultrasonic diagnosis of polycystic ovaries in many of these studies was not confirmed by hormonal assay or laparoscopy and most of these reports did not correlate the ultrasonic appearance of PCO to the clinical, hormomal and laparoscopic findings.[6]

The aim of this study was to review the ultrasonic appearance of polycystic ovaries and to correlate it to the different clinical, hormonal, and laparoscopic findings of polycystic ovarian disease.

Material and methods

Twenty patients with PCOD (18 to 35 years) were thoroughly examined clinically, and their findings were recorded. None of the patients received hormonal treatment for at least 3 months before the study. Clinical findings included secondary amenorrhea (45%), oligomenorrhea (35%), primary infertility (94%), hirsutism (70%), obesity (80%), galactorrhea (35%), and acne (15%). Ovarian size as detected by pelvic examination was recorded.

Repeated basal plasma samples were taken at 8 AM under basal conditions and assayed with use of standard radioimmunoassay kits for the following hormones: luteinizing hormone, follicle-stimulating hormone, prolactin, estradiol-17β, estradiol-17β, estrone, progesterone, testosterone, androstenedione and dehydroepiandrosterone sulfate. Each sample (12 ml) was the aliquot of three smaller samples taken at 30-minute intervals. Samples were taken daily for three consecutive days during each of the follicular, periovulatory, and luteal phases of the baseline cycle.

Pelvic ultrasound examination was performed with use of a 3.5 MHz sector real-time transducer (Emisonic 4200). After visualization of the ovaries with use of the full-bladder technique and with the ovarian artery as a landmark, the following sonographic findings were recorded: (1) ovarian size (½ × length × width ×

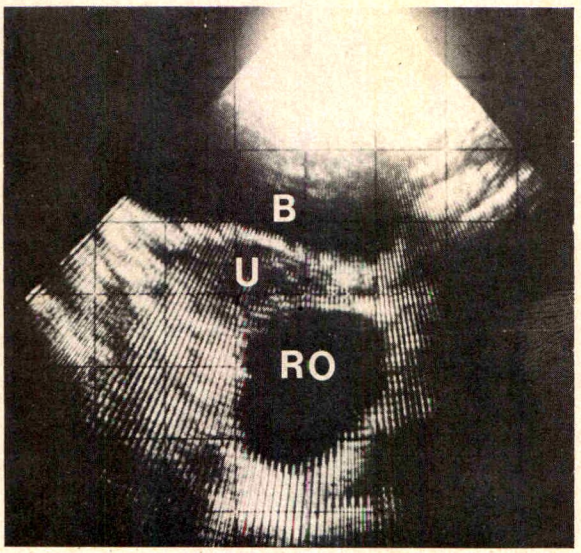

Fig. 1. Oblique scan showing enlarged right ovary (single cyst). *B*, bladder; *RO*, right ovary; *U*, uterus.

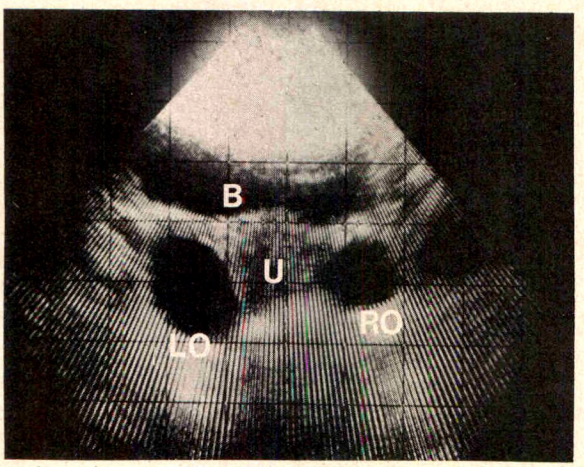

Fig. 2. Transverse scan showing bilaterally enlarged cystic ovaries (single cyst). *B*, bladder; *RO*, right ovary; *LO*, left ovary; *U*, uterus.

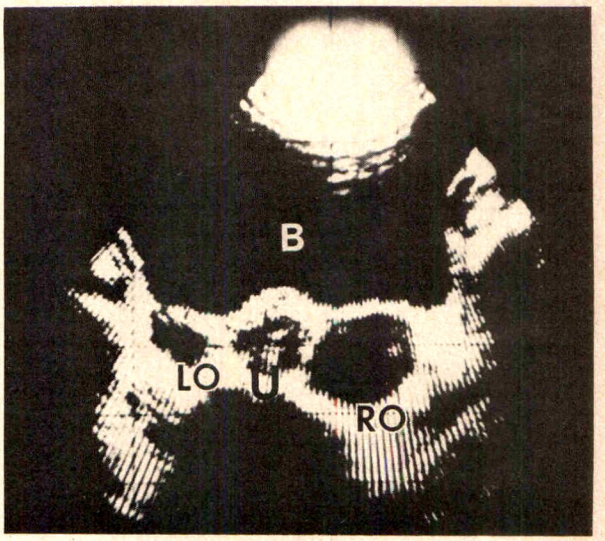

Fig. 3. Transverse scan showing bilaterally enlarged ovaries (more on the right side) with intraovarian trabeculae demonstrating multiple small cysts. *B*, bladder; *RO*, right ovary; *LO*, left ovary; *U*, uterus.

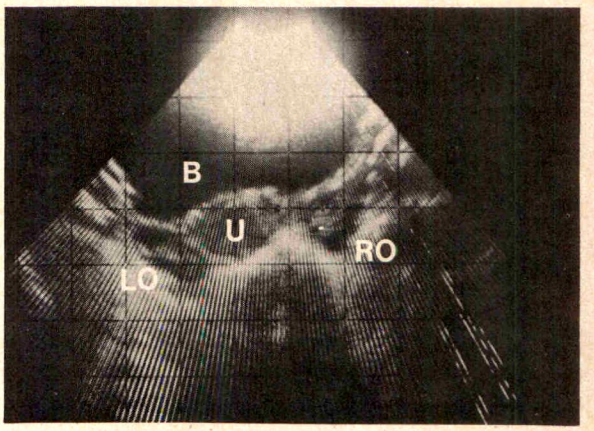

Fig. 4. Transverse scan showing bilaterally enlarged isoechoic ovaries. *B*, bladder; *RO*, right ovary; *LO*, left ovary; *U*, uterus.

thickness)[6]; (2) maximum surface area (maximum diameter × minimum diameter × 0.785)[6]; (3) ovarian echogenicity; (4) presence or absence of ovarian cysts, their number, and size; (5) ovarian margin, whether regular or irregular; (6) ovarian capsule, whether thick or thin.

All sonograms were performed early in the cycle in oligomenorrheic patients or at random in amenorrheic ones. To differentiate normally developing graafian follicles in normal ovaries from follicles in normal-sized polycystic ovaries, repeat scans were sometimes performed. Follicles in polycystic ovaries are bilateral and persist on serial examinations, since ovulation does not occur, whereas normal ovaries will show regression of follicles and development of a corpus luteum on scans obtained later in the menstrual cycle.

Laparoscopy was performed as part of an infertility workup and the ovarian size, shape, capsule, and surface were recorded.

Results

The ovaries were palpable in eight patients (40%) by careful vaginal examination of the unanesthetized patient.

Ultrasound findings. Both ovaries were enlarged in 15 patients (75%) with a mean ovarian size of 15.46 ± 2.5 cm^3 and a range of 12.94 to 20.28 cm^3 (average normal ovarian size is 7.8 ± 0.4 cm^3). The ovaries were of normal size in five patients (5%), with a mean ovarian size of 7.93 ± 0.49 and a range from 6.37 to 7.5 cm^3. The maximum ovarian surface area of the group studied was 9.75 ± 3.38 cm^2 with a range from 6.37 to 20.28 cm^2. The ultrasonic appearance of polycystic ovaries (Figs. 1-4) showed one of three pat-

† Prolactin (mean of three samples) >20 ng/ml.

terns: (1) isoechoic, with no discernible cysts (four patients); (2) hypoechoic, with multiple small cysts of <1 cm in diameter (11 patients); (3) hypoechoic, with single cyst of >1 cm in diamter (five patients).

The ovarian margin was regular in 17 patients (85%) and irregular in three patients (15%). Ovarian capsule was thick (lumpy and echogenic) in 18 patients (90%).

Basal hormonal evaluation showed anovulatory luteal-phase progesterone in all patients (100%), elevated luteinizing hormone/follicle-stimulating hormone ratios in 16 patients (80%), elevated testosterone levels in 16 patients (80%), elevated androstenedione levels in 15 patients (75%), normal or low estradiol-17β levels in 16 patients (80%), high estrone levels in seven patients (35%), and high dehydroepiandrosterone sulfate levels in three patients (15%) as compared to normal control values. Nine patients (45%) were hyperprolactinemic (basal prolactin >20 mg/ml), and 11 patients (55%) were normoprolactinemic.

There was no significant relationship between the ultrasonic ovarian size and any of the hormones studied. The hyperprolactinemic subgroup of polycystic ovarian disease showed larger ovarian size compared to the normoprolactinemic subgroup, but the difference (Table 1) was not statistically significant.

Comparison between patients with polycystic ovarian disease with normal-sized versus enlarged ovaries showed that obesity, amenorrhea, hirsutism, hyperprolactinemia, elevated testosterone and dehydroepiandrosterone sulfate levels, and normal or low estrone levels occurred more often in the group with enlarged ovaries (93% vs. 40%, 46.7% vs. 40%, 80% vs. 60%, 46.7% vs. 40%, 86.7% vs. 60%, 20% vs. 0%, and 86.7% vs. 60%, respectively). On the other hand, oligomenorrhea, elevated luteinizing hormone/follicle-stimulating hormone ratio, and elevated androstenedione and estrone levels were more common in the group with normal-sized ovaries (40% vs. 33.3%, 100% vs. 73.3%, 100% vs. 66.7%, and 60% vs. 26.7%, respectively).

Laparoscopic findings. The uterine size, surface, and mobility were normal in all patients. The tubes looked normal and were bilaterally patent in 19 patients. One patient had evidence of salpingitis with unilateral fimbrial obstruction and peritubal adhesions.

The ovaries showed no signs of ovulation in all patients (100%). Both ovaries were enlarged with a smooth surface and thick white capsule in 15 patients (75%). The ovaries were normal in size with a sclerocystic surface in five patients (25%). Laparoscopy confirmed ultrasonic findings regarding ovarian size, surface, and capsule in all patients.

Comment

This study is one of few reports on the accuracy of ultrasonic diagnosis of polycystic ovaries that were confirmed by hormonal and laparoscopic criteria. Hann et al.[3] studied the ultrasonic appearance of 28 patients with polycystic ovarian disease. He found that 71% of the cases had bilaterally enlarged ovaries, which is close to our findings. The mean ovarian size in his case was 14 cm^3. Thirty-nine percent of his cases showed discrete cysts, 25% were hypoechoic, and 7% were isoechoic to the uterus.

Parisi et al.[6] studied the ultrasonic appearance of 26 patients with polycystic ovarian disease, seven of which cases were confirmed histologically either by surgery or by laparoscopy. The maximum ovarian surface area in their study ranged from 12.9 cm^2 to 17.3 cm^2 with an average of 12.9 ± 2.6 cm^2. In 19 of their patients the ovarian structure was made of many small cystic spaces, approximately 0.5 cm in diameter. In two other cases a cyst of 1.5 cm in diamter was present inside one ovary. In the remaining five patients the ovarian structure was formed of many thick echoes arranged along parallel lines. Parisi et al.[7] found that the edges of polycystic ovaries were lumpy and echogenic. Orsini et al.[8] observed four ultrasonographic ovarian patterns in polycystic ovarian disease: (1) enlarged cystic, (2) enlarged solid, (3) normal-sized cystic, (4) normal-sized solid.

In our study, clinical examination showed enlarged ovaries in only eight of 15 patients proved to have en-

larged ovaries by ultrasound. This emphasizes the superiority of ultrasound in estimating ovarian size in polycystic ovarian disease.

This study showed that regarding ovarian morphology, ultrasound studies were equally as informative as laparoscopic ones. The noninvasive character of ultrasound makes repeat scans and follow-up of ovarian response to therapeutic measures possible.

Ultrasound evaluation of amniotic fluid: Outcome of pregnancies with severe oligohydramnios

Adrien Bastide, M.D., Frank Manning, M.D., Christopher Harman, M.D., Ian Lange, M.D., and Ian Morrison, M.D.

Winnipeg, Manitoba, Canada

Severe oligohydramnios, defined as a condition in which the largest pocket of amniotic fluid measures less than 1 cm in its vertical axis as determined by an ultrasound method, was observed in 113 patients in a population of 15,431 referred high-risk patients (0.7%). In all cases, intervention took place unless there was a recognized structural anomaly or exteme prematurity. Overall gross perinatal mortality was 132.7/1000, and the incidence of major anomaly was 13.3%. With intervention the corrected perinatal mortality rate was 17.7/1000, a rate not significantly different from that observed in the entire population. All end points of perinatal mortality were significantly increased in patients with severe oligohydramnios, in comparison with randomly selected control subjects with normal amniotic fluid. These findings are interpreted to indicate that severe oligohydramnios in a structurally normal fetus is an indication for delivery. (Am J Obstet Gynecol 1986;154:895-900.)

Key words: Oligohydramnios, identification by ultrasound, perinatal outcome

Oligohydramnios has long been recognized as a clinical hallmark of impending severe perinatal compromise. Prenatal estimation of the volume of amniotic fluid, when done by physical examination alone, may be difficult and is frequently inaccurate. Since amniotic fluid and its distribution throughout the uterine cavity is readily identified by ultrasound examination, this objective method of evaluation may be used to estimate amniotic fluid volume and its adequacy. Semiquantitative estimation of amniotic fluid volume by an ultrasound method is a component part of fetal biophysical profile scoring.[1] The purpose of this study was to determine the perinatal outcome with the use of perinatal mortality and selected end points of perinatal morbidity in consecutive patients with a singleton pregnancy, intact membranes, and severe oligohydramnios on the last observation before delivery. These statistics were then compared with similar statistics for the entire referral population and morbidity statistics for a randomly selected subgroup to determine the difference in outcome, if any, between these groups.

Material and methods

Semiquantitative amniotic fluid volume assessment is an integral part of fetal biophysical profile scoring, the primary method of fetal risk determination used at this center.[1] The method involves identification, by dynamic ultrasound, of the largest pocket of amniotic fluid and measurement of this pocket to record the maximal diameter in the vertical plane. Severe oligohydramnios in this study is defined by a generalized decrease in amniotic fluid throughout the uterine cavity such that the largest vertical diameter of any pocket is equal to or less than 1 cm (Fig. 1). In the study period from January 1, 1980, to May 31, 1985 (65 months) the perinatal outcome was reviewed in consecutive patients who had a singleton fetus that was alive at initial presentation, who had intact membranes, and who exhibited severe oligohydramnios. In all patients at all visits, in addition to the recording of amniotic fluid volume, a fetal biophysical profile score was determined and an evaluation for congenital anomalies was done. All patients with severe oligohydramnios were delivered within 48 hours of confirmation of the findings unless a major developmental anomaly incompatible with life was recognized or the gestational age at diagnosis was less than 27 weeks. These results were contrasted with perinatal mortality and the incidence of major anomaly observed in the entire referral population (N = 15,431) and with the end points of perinatal morbidity as determined in a random sample of patients with normal amniotic fluid on the last test before delivery (N = 1000).

End points used to judge perinatal outcome included the following:

1. Perinatal death was defined as the death of a fetus

whose birth weight was 500 gm or more or whose gestational age at death was at least 24 completed weeks or as the death of a live-born infant within the first 28 days of neonatal life. Corrected perinatal death was defined as the death of a structurally normal perinate.

2. Fetal distress was defined as an abnormal fetal heart rate monitoring record either alone or in combination with other abnormal fetal biophysical variables (biophysical profile score <4).

3. Five-minute Apgar score was judged by an independent observer, in most instances either an anesthetist or a neonatologist. A 5-minute Apgar score of <7 was considered abnormal.

4. The incidence of intrauterine growth retardation was defined as a birth weight of less than the tenth percentile for gestational age and sex as indicated by a sea level nomogram.[2]

5. The presence of major structural congenital anomalies.

6. The frequency of admission to an intensive care nursery and the total number of neonatal hospital days were calculated.

Statistical analysis was by nonparametric tests, using χ^2 analysis in most instances. Fisher's exact test was used when a variable frequency of ≤5 was recorded. Differences were considered statistically significant when the p value was equal to or less than 5%.

Population logistics. Semiquantitative amniotic fluid volume determination by an ultrasound method was obtained serially in 15,431 consecutive referred high-risk patients. The study population consists of 113 patients (0.73%) in whom severe oligohydramnios, as defined, was observed on the last test before delivery. Perinatal mortality in the study group was contrasted with the rate observed in the referral population. Perinatal morbidity results in the study group were compared with the same end points obtained in 1000 randomly selected patients with normal amniotic fluid volume observed on the last test before delivery. The primary indications for initial referral to fetal assessment for the entire referred population and the subset with severe oligohydramnios are listed in Table I. No significant difference in indication for referral is noted between these groups, although referral because of a clinical suspicion of intrauterine growth retardation was more than twice as frequent in patients with subsequently proved severe oligohydramnios.

Results

In the 113 study patients the mean maternal age was 26.6 years (range 16 to 47) and the mean parity was 1 (range 0 to 7). The gestational age at delivery ranged from 27 to 44 completed weeks, with most patients (83.2%) delivering at or after 36 completed weeks (Fig. 2). Of 113 patients, 27 (23.9%) were at 42 or more completed weeks at delivery (Fig. 2).

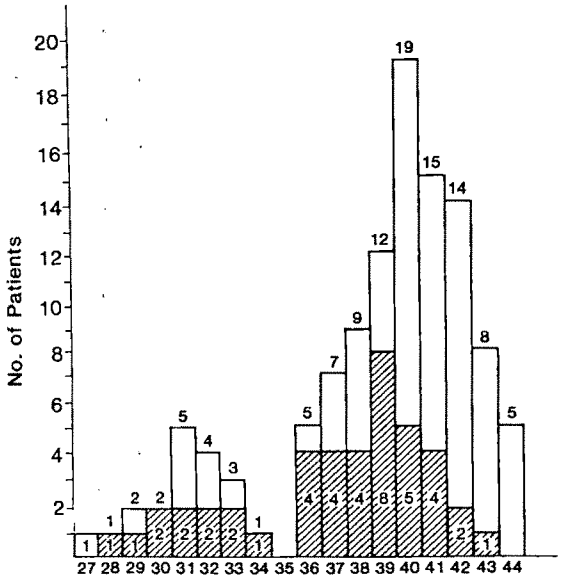

Fig. 2. Distribution of patients with severe oligohydramnios (N = 113) by gestational age at the time of delivery. *Hatched lines*, neonate with intrauterine growth retardation (N = 43).

By protocol, delivery was initiated within 48 hours of recognition of severe oligohydramnios unless there was an associated lethal fetal anomaly complex or extreme prematurity (<27 completed weeks). In 14 patients, delivery was delayed for more than 48 hours and up to 14 days; in 12 of these 14 patients the delay was related to the finding of a lethal anomaly, and in two the delay was due to extreme prematurity. Of 113 patients with severe oligohydramnios, 99 patients were delivered within 48 hours of the last test (87.6%). In 35 of these 99 patients (35.3%) delivery was by cesarean section.

Perinatal outcome. Fifteen perinatal deaths occurred in 113 patients with severe oligohydramnios, giving a gross (uncorrected) perinatal mortality rate of 132.7/1000 (Table II); nine of these 15 deaths occurred as stillbirths. Most stillbirths occurred within 1 week of the diagnosis of oligohydramnios, and the longest interval between diagnosis and death was 11 days. Of the 15 deaths, 13 (86.6%) were due to associated major anomalies: seven fetuses or neonates died of multiple malformations, five of bilateral renal agenesis, and one of a neural tube anomaly. Two other infants with congenital anomalies survived. The corrected perinatal mortality was 17.7/1000 (two deaths). Both of these deaths in structurally normal fetuses occurred in the antepartum period and before 27 completed weeks of gestation (26 and 26.5 weeks, respectively). Since obstetric intervention was not considered before 27 weeks' gestation, these two deaths were considered nonpreventable. Whereas the gross perinatal mortality for patients with severe oligohydramnios (132.7/1000) was significantly higher than the rate observed for the entire referral population (14.2/1000; $p < 0.01$, χ^2 anal-

ysis), the corrected perinatal mortality rate for these two populations (17.7 and 7.35/1000, respectively) did not vary significantly (Table II).

In 99 patients with severe oligohydramnios, perinatal salvage was considered feasible, and for these patients delivery was accomplished within 48 hours of the initial diagnosis. In 38 of these 99 fetuses (38.4%), fetal heart rate monitoring yielded abnormal results either alone or in combination with other abnormal biophysical variables (Table III). This rate of fetal distress was significantly greater than the similar rate observed in the control referred population (7.8%; $p < 0.01$, χ^2 analysis). The rate of fetal distress in patients in whom recognition of severe oligohydramnios prompted obstetric intervention did not vary significantly from previously published results in similar patients managed conservatively[1] (28.8%) (Table III). In 15 of 99 patients (15.2%) the 5-minute Apgar score was less than 7, a rate significantly higher than that observed in the control referral population (4%; $p < 0.05$, χ^2 analysis). Comparison of the incidence of low 5-minute Apgar scores between treated patients with severe oligohydramnios (15.2%) and previously published nontreated cases (23.6%) revealed no significant difference (Table III). Intrauterine growth retardation, defined as a birth weight of less than the tenth percentile for gestational age and sex, occurred in 38 of 104 live-born infants (36.5%), a rate significantly higher than the rate observed for the control referral population (5.5%; $p < 0.01$, χ^2 analysis). Of these 38 fetuses, 25 (65.8%) were suspected to have intrauterine growth retardation on clinical grounds, prompting initial referral. Considered collectively, 15 of 113 patients with severe oligohydramnios (13.3%) delivered a child with a major developmental anomaly. The rate of major anomaly in the control referral population was 0.7%. These differences were highly significant ($p < 0.001$, χ^2 analysis). Of 104 live-born fetuses, 45 (43.3%) required admission to an intensive care nursery, in comparison with 6.5% of the control referral population ($p < 0.01$, χ^2 analysis). The average hospital days for neonates delivered with severe oligohydramnios was 10.4 days (range 2 to 63); comparable statistics for the control referral population were not readily available.

Comment

Severe oligohydramnios, as defined by an ultrasound method in this study, is an unusual finding in referred high-risk pregnancies, complicating only 0.73% of all cases. A similar low frequency (0.85%) of severe oli-

gohydramnios is reported by Chamberlain et al.[3] in a similar population with the use of the same diagnostic criteria. Severe oligohydramnios, despite its infrequency, appears to be an important sign of perinatal compromise. All measures of perinatal mortality and morbidity applied to patients with severe oligohydramnios were significantly increased when compared with rates observed in the entire referral population or the randomly selected control group. Several of these differences warrant further comment. First, the gross perinatal mortality rate was significantly higher among patients with severe oligohydramnios in comparison with the entire referral population, a difference that was due primarily to the increased frequency of lethal malformation among the former group (13.3% and 0.7%, respectively). The corrected perinatal mortality rate, achieved by exclusion of deaths caused by major anomaly between the two groups, did not differ significantly (Table II). In contrast, the corrected perinatal mortality in patients with severe oligohydramnios in whom delivery was initiated (17.7/1000) was significantly lower than the rate reported in a similar population managed conservatively (89.9/1000[1]; Table II). We interpret these findings as indicating that intervention for severe oligohydramnios resulted in an improved probability of perinatal survival. This supposition remains open to challenge because the two groups compared, although subjected to the same diagnostic criteria, come from different institutions and were seen during different periods.

The incidence of low 5-minute Apgar score and those of fetal distress and admission to an intensive care nursery were all sharply and significantly increased in patients with severe oligohydramnios, in comparison with the random control group (Table III). The incidence of low 5-minute Apgar scores in patients delivered because of severe oligohydramnios (15.2%) did not significantly differ from that observed in similar patients managed conservatively (23.6%[1]). Thus, despite intervention in patients with severe oligohydramnios, the probability of low 5-minute Apgar scores remains high, confirming the increased probability of perinatal compromise in such cases. These end points, used to judge perinatal morbidity, although prospectively and in a uniform manner, must be considered "soft" measures of compromise and subject to observer bias. Nonetheless, since the object of perinatal intervention is to reduce morbidity as well as mortality, the increased incidence of these more subjective measurements of perinatal morbidity must be considered in management decisions regarding patients with severe oligohydramnios.

The incidence of developmental structural anomalies and that of intrauterine growth retardation, both more objective measures of perinatal compromise, were considerably increased in patients with severe oligohydramnios. Renal agenesis was observed in 4.4% of patients with severe oligohydramnios; this association may be expected because fetal urine is a major source of amniotic fluid in later gestation. The diagnostic criteria for diagnosis of renal agenesis are well established, including both ultrasound assessment for presence of renal tissue and serial fetal bladder volume determination to confirm normal renal function.[4] Yet pharmacologic tests of fetal urine production must be interpreted with caution.[5] We were surprised to find the relatively high frequency of major anomalies involving organ systems other than the genitourinary tract in patients with severe oligohydramnios (eight cases). The basis for this association remains unexplained.

The incidence of intrauterine growth retardation was significantly increased among patients with severe oligohydramnios (38%, 43 of 113 cases); yet most patients with severe oligohydramnios did not deliver a fetus with intrauterine growth retardation (62%). The combination of a clinical suspicion of intrauterine growth retardation (prompting initial referral for fetal assessment) and documented severe oligohydramnios yielded a true incidence of oligohydramnios of 69.8% (30 of 43 cases). This rate, although high, is less than that reported previously for this association by Manning et al.[6] (90%). These differences almost certainly reflect differences in size-versus-dates discrepancies, prompting initial referral for suspected intrauterine growth retardation. The mechanism by which oligohydramnios is associated with increased frequency of perinatal compromise remains conjectural. Intrauterine fetal hypoxemia and/or asphyxia may cause redistribution of cardiac output away from the fetal lung and kidney, the two major sources of amniotic fluid in later gestation, and therefore may be the cause of progressive oligohydramnios.[7] The observation of a diminished urine production rate, measured indirectly by ultrasound assessment of bladder volume in fetuses with intrauterine growth retardation, supports this contention.[8] In contrast, in some instances, oligohydramnios, produced by whatever mechanism, may ultimately result in cord compression.[9] Therefore, in such cases, oligohydramnios may also be the cause of perinatal compromise. It is likely that in many fetuses with severe oligohydramnios, both mechanisms of perinatal compromise may be operant.

In summary, these data suggest that the antenatal detection of severe oligohydramnios may indicate a high probability of perinatal compromise, together with an increased risk of perinatal death. In such patients, initial assessment must include evaluation of fetal structure with particular, but not exclusive, reference to the fetal genitourinary tract. In the fetus judged to be structurally normal, we interpret these findings to

indicate that obstetric intervention is both warranted and indicated.

External cephalic version of the breech presentation under tocolysis

John C. Morrison, M.D., Ray E. Myatt, M.D., James N. Martin, Jr., M.D., G. Rodney Meeks, M.D., Rick W. Martin, M.D., Edsel T. Bucovaz, Ph.D., and Winfred L. Wiser, M.D.

Jackson, Mississippi

External cephalic version with tocolysis at or near term has been advocated to avoid cesarean birth for breech presentation. In our institution this maneuver was successfully performed in 207 of 304 parturients without major complications, and all but six had vertex presentation at delivery. The success of version was inversely correlated with gestational age but was not correlated with ease of version, number of attempts, or placental location. When this 3-year period was compared with the previous three years (1979 to 1981), there was a significant reduction in the number of breech presentations during labor, whereas the total delivery rate remained relatively constant over the 6-year period. It appears that in a carefully selected population, external version near term can be used safely to reduce the need for abdominal birth because of breech presentation. (Am J Obstet Gynecol 1986;154:900-3.)

Key words: Tocolysis, external cephalic version, breech presentation

It is well known that vaginal delivery in a breech presentation involves a greater risk of perinatal mortality and morbidity than that in a cephalic presentation.[1] The increased damage in breech infants at term frequently appears to be the result of traumatic delivery in cases showing slight degrees of disproportion not easily predicted in advance by clinical or radiologic study.[2] It has been suggested that cesarean birth should be employed more often in an effort to reduce neonatal damage at term with breech presentation, but this strategy increases maternal mortality and morbidity. Two management schemes to address this dilemma have evolved: one embraces routine abdominal delivery for breech presentation, whereas the other advocates scoring systems to select patients for "safe" vaginal delivery.[3, 4] Both management techniques, however, result in an increased cesarean birth rate with its inherently high maternal morbidity rate, and neither attacks the primary problem of the breech presentation itself.

Several authors have advocated early external cephalic version as a simple and safe method to reduce the incidence of breech presentation at term.[5, 6] Unfortunately, the earlier the version attempt, the more

Table I. Presentation in labor after version

Version attempt	*No. of patients*	*Presentation*		*Method of delivery*	
		Vertex	*Breech*	*Vaginal*	*Abdominal*
Successful	207	201	6	182	25
Unsuccessful	97	0	97	37	60

likely the fetus is to return to the breech presentation, whereas the later the version, the less likely the attempt will succeed.[6] Further, some care providers believe that the procedure may pose excessive fetal risk in the form of placental separation, cord accident, or Rh sensitization.[5]

To circumvent some of these problems, Saling and Muller-Holve[7] proposed the practice of external cephalic version using β-sympathomimetic tocolysis after 37 weeks' gestation. This method offers several potential advantages over early version: (1) spontaneous reversion to breech is uncommon, (2) if fetal distress occurs, the fetus is mature enough for immediate delivery, and (3) uterine relaxation should facilitate easier manipulation. More recently, others have corroborated those findings.[8, 9] Reports on the use of tocolysis in a larger number of patients to access the potential complications to mother and fetus, as well as its impact on the mode of delivery, were not available in the literature. For that reason a study was undertaken in our institution.

Material and methods

During a 3-year period (January, 1982, to December, 1984), 304 normal, "low-risk" patients with breech presentations at greater than 36 weeks' gestation were selected for attempted breech version and agreed to the study protocol, which had been approved by the Institutional Review Board of the University of Mississippi Medical Center. Details of the procedure, potential benefits and risks, and the safeguards to be employed were explained to the patient. The decision to perform the procedure was contingent on her understanding of the protocol. Patients were entered in the study after informed consent forms had been signed. Patients with the following conditions were excluded: (1) maternal cardiac disease, (2) hypertension, (3) premature rupture of the membranes, (4) intrauterine growth retardation, (5) previous uterine surgery, (6) multiple gestation, (7) placenta previa, and (8) oligohydramnios. Requirements for inclusion into the study included (1) gestation ≥36 weeks, (2) breech presentation, (3) absence of any contraindication (exclusion criteria), (4) normal sonographic appearance of fetus, placenta, and amniotic fluid volume, and (5) a reactive nonstress test.

The procedure was conducted in the labor and delivery area. All patients underwent a thorough real-time ultrasound B scanning examination, a nonstress test, and a pelvic examination. A normal real-time B scan was defined as follows: singleton fetus in the breech position; adequate fluid (at least a 1.0 cm pocket of fluid); biparietal diameter >8.5 cm but <10.5 cm and an absence of gross fetal anomalies; or placenta previa. Patients were placed in the lateral semirecumbent position with left uterine displacement. An intravenous line was initiated with a crystalloid solution. A nonstress test was performed, and after a reactive pattern was noted, ritodrine hydrochloride was infused at 0.1 mg/min for 15 minutes prior to and during the procedure.

Maternal heart rate and blood pressure were continuously monitored, as was the fetal heart rate. Version was accomplished by the classic "forward roll" technique if the fetal spine and head were on the same side of the maternal midline. The "back flip" method of Saling and Muller-Holve[7] was used if the initial method failed. A second examiner manipulated the opposite fetal pole or assisted by vaginal elevation of the breech. The procedure was interrupted if patient discomfort became severe or if fetal heart rate decelerations were noted. In many cases, multiple attempts at version were performed. Once the fetus was turned satisfactorily, the β-sympathomimetic infusion was discontinued and the fetus was maintained in the new attitude until uterine tone returned. Real-time B scan was used to confirm version success. For Rh-negative, unsensitized patients, Rh immune globulin was administered following version. After the procedure, fetal heart rate monitoring was continued until a reactive nonstress test was noted.

The following maternal, fetal, and newborn variables were tabulated: (1) ease of version, defined according to the amount of time required to complete the maneuver and the number of attempts (an easy version was completed within 1 minute, with one or two attempts; a moderately difficult version was between 1 and 5 minutes, with two to five attempts; and a difficult version required longer than 5 minutes, with more than five attempts); (2) discomfort during the procedure (patients were asked to describe the procedure as painless or as mildly, moderately, or severely uncomfortable); (3) maternal heart rate and blood pressure; (4) fetal heart rate and uterine activity during and following the version; (5) vaginal bleeding, timing of rupture of the

membranes, and onset of labor; (6) intrapartum presentation and route of delivery; and (7) evidence of morbidity during the neonatal period. The χ^2 analysis was used to detect statistical differences, and a p value of <0.05 was considered significant.

Results

Version was successful in 207 of 304 patients (68%). In all of the successful versions, the fetuses had vertex presentations during labor, except six that reverted spontaneously to breech; five of them were delivered by cesarean birth (Table I). A subseptate uterus and a partial placenta previa were found during a cesarean delivery in two of these five cases. The abdominal delivery rate among the subjects (201) with a vertex presentation was 10%, and in no case was the indication for cesarean birth thought to be associated with the version. Of the 97 futile attempts, all deliveries were breech births and 62% were operative births (Table I).

Of the successful versions, the vast majority were deemed easy (167), whereas 31 were moderately difficult and nine were difficult. Of these 207 parturients, 66 patients reported the procedure to be painless, 118 noted mild discomfort, and 23 described the version to be moderately uncomfortable. No patients reported severe or intolerable pain. Among the unsuccessful group, severe pain was the reason to discontinue the procedure in 12 subjects, whereas the type of pain noted subjectively was equally distributed (none, mild, moderate) among the other 85 patients in this group.

In none of the 304 patients did rupture of the membranes, vaginal bleeding, or onset of labor occur within 24 hours of the attempted version. In none of the cases did uterine rupture or catastrophic maternal-fetal events occur. Fetal heart rate abnormalities (tachycardia, bradycardia, change in baseline, variable decelerations) occurred in 18% of the subjects during or after the procedure, but all responded to conservative management (oxygen, change in position, fluid administration with observation). Fetal heart rate abnormalities were a reason to abort version attempts in only six patients and were not related to the number of attempts or the ease of version. In no case was emergency delivery necessary. Likewise, hypotension, tachycardia, or other maternal side effects of the tocolytic agent did not necessitate abandonment of the procedure in any of the 304 patients. The total time for the procedure from entry into the delivery area until discharge was 160 ± 43 minutes among the successful group and 180 ± 51 minutes in those with failed version attempts.

Table IV. Mode of delivery for singleton breech fetuses at term

	1979-1981		1982-1984	
	n	%	n	%
All deliveries	12,942		13,221	
Cesarean birth (breech)	359	61	216	59
Vaginal delivery (breech)	230	39	150	41
Total	589		366*	

*p < 0.001.

A significant difference in version success rate was noted when gestational age at the time of version was compared (Table II). At gestatational ages of 37 to 39 weeks, 179 of 243 attempts (73%) were successful in comparison with 45% (28 of 61) at 40 to 43 weeks (p < 0.001). In contrast, no difference was apparent in version success rate when placental location was used as the discriminator (Table III). Version was unsuccessful in 45 of 128 patients (46%) with anterior placentation and in 52 of 176 patients (54%) with posterior placental placement (p = 0.3).

Careful examination during labor and at delivery disclosed no increased incidence of maternal-fetal-neonatal abnormalities related to the procedure. No increase in meconium-stained fluid, abnormal intrapartum fetal heart rate tracings, low Apgar scores, or neonatal or placental trauma was noted among the total group in comparison with a like number of term infants whose mothers did not undergo an attempted version. In none of the Rh-negative parturients was sensitization noted at delivery.

Comment

The data from this study and a review of the literature leave little doubt that external cephalic version near term will reduce the incidence of breech presentation in labor. Between 90% and 97% of successful versions can be expected to remain as vertex presen-

tations until the onset of labor.[8-10] In addition, few breech fetuses spontaneously convert to the vertex presentation after 36 weeks' gestation.[6] In this study, 68% of the breech presentations were converted to vertex successfully, and all but six fetuses presented in this attitude; figures were similar to those in other series.[7-9]

The impact of breech version on the cesarean birth rate has not been well defined, primarily because of diverse strategies regarding the management of breech presentations at term and because of the lack of large numbers of patients in most studies. We have been challenged to reduce the number of abdominal deliveries.[11] In our study, only 10% of successful versions required cesarean section, in comparison with 60% of the failure group. As shown in Table IV, the number of breech deliveries during the study period was significantly reduced ($p < 0.001$) in comparison with the preceding 3 years, although the total delivery rate increased by 5.4%. The percentage of cesarean versus vaginal deliveries did not differ during both periods for patients with a breech presentation during labor. As a result, the abdominal delivery rate was reduced by this strategy. Obviously, the higher the cesarean birth rate for breech presentation at term in any institution, the greater will be the impact of a program of external version.

The most pertinent question, other than the success of this modality, involves the safety of the procedure.[10, 12] In this study, no intrauterine deaths or neonatal losses attributed to a cord accident or placental abruption occurred. Other studies offer similar results.[8-10] Strict insistence on a normal fetal heart rate pattern both before and after version, as well as a normal real-time B scan, identifies the potentially compromised fetus and/or placental unit. Careful intraprocedure monitoring allows repetitive manipulation in individual cases where fetal heart rate irregularities transiently occur.

In conclusion, these data indicate that in the carefully monitored and selected patient population, external version, near term, of the breech presentation can safely increase the vertex attitude by the onset of labor. This strategy would appear to reduce the need for cesarean birth. Constant vigilance, however, is necessary during the procedure to ensure that one does not damage the fetus or the parturient.

Prophylactic tocolysis of twins

James A. O'Leary, M.D.
Jacksonville, Florida

The prophylactic use of oral terbutaline was studied in 28 normal, healthy, low-risk women with twin gestations. The mean birth weights were significantly increased over those in a similar group of control patients. (AM J OBSTET GYNECOL 1986;154:904-5.)

Key words: Multiple pregnancy, prophylactic tocolysis

Greater attention is being directed at the twin gestation since it contributes disproportionately to the total perinatal morbidity and mortality in the United States and elsewhere. The most important perinatal factors responsible for this are the significantly higher incidence of premature labor and infants of low birth weight. The risk of pregnancy loss in twin gestation remains three or more times that of singleton pregnancy and respiratory distress syndrome is the most common cause of death.

Early detection of a multiple gestation is a critical first step in any effort to reduce the obvious risks of prematurity. Recently, an increasing amount of attention has been directed at attempting to improve the perinatal outcome in this special group of high-risk mothers. One such logical attempt is the prophylactic pharmacologic reduction of uterine activity.

Although bed rest has been an important part of preventing premature labor, more recent clinical studies[1] have observed that 70% of twin perinatal mortality occurs before the thirtieth week of gestation. Thus if any protocol is to be effective it should be instituted well before this time. It has been emphasized repeatedly that the most effective regimens are those resulting in a decreased incidence of prematurity. Because any preventive measure requires early detection, several authors have suggested more frequent ultrasonographic examinations to detect twins. Once twins are detected, most reports have recommended bed rest as the single most effective treatment for the prevention of premature labor.

The purpose of this prospective study was to determine if an orally administered prophylactic tocolytic agent and modified bed rest regimen would be superior to bed rest alone as a method for the prevention of labor.

Case material and outcome

A group of 60 healthy women with low-risk twin gestations detected between 20 and 30 weeks of gestation were included in this prospective study. All patients were of low socioeconomic status and attended the prenatal clinics at University Hospital of Jacksonville. The age and parity distribution was similar in both groups (Table I). Women with complicating factors such as diabetes, prior premature labor, incompetent cervix, and hypertension were not included in the study. After the diagnosis was made all women were advised to stop working and institute maximum bed rest and as much abstinence from intercourse as reasonably possible. Patients were not admitted to the hospital but were followed up in a special twin clinic. Pelvic examinations were rarely performed.

The study group of 28 women were started on a regimen of terbutaline by mouth, 2.5 mg every 6 hours. If uterine activity was noted the interval was shortened to every 4 hours, and rarely the dose was increased to 5 mg. These patients continued on the drug regimen until 35 weeks' gestation. The control group consisted of 32 women treated in a similar fashion who did not receive terbutaline. Although the study was prospective and all patients were treated the same way by the same team it was not possible to blind the medications. Pa-

tients were informed that the drug terbutaline was not approved for this use but was frequently used in this institution for premature labor. The treatment protocol was submitted to the Committee on Human Experimentation and approved.

The time of entry into the study was similar in both groups. The mean length of gestation was longer in the study patients and the additional days the infant was retained in utero was greater for the study patients (Table II).

A *t* test for independent means for birth weights was used. A significant difference in the mean was observed ($p = 0.007$). The standard deviation of the mean was 478.9 in the control group and 554.2 in the study group, while the standard error of the mean was 84.7 and 104.7, respectively.

Although some reports have suggested starting bed rest after the twenty-ninth or thirtieth week, the recent data of Keith et al.[3] show this is clearly too late, as more than 70% of the perinatal mortality associated with twins occurs before the thirtieth week. This would suggest the potential benefit of the early use of terbutaline. This critical period of <30 weeks has been previously alluded to by Manlan and Scott.[4] Hospitalization for bed rest after 30 weeks did not decrease perinatal mortality. Therefore, if hospitalization for bed rest and/or the use of prophylactic tocolysis can be expected to exert any impact on both the survival and the quality of survival of these infants, it must include the 25- to 30-week period.

Little benefit can be expected after 32 weeks. Rather, after this time, intrauterine growth retardation becomes the most important cause of prenatal wastage, constituting 30% in the study of Keith et al. with most such cases presenting as preterm stillbirths. Although bed rest should be encouraged after the thirty-second week, of greater importance is increased attention to antenatal assessment. The place of tocolytics after ≥32 weeks will require further evaluation.

Comment

Having diagnosed twins, the obstetrician is confronted with what preventative measures to institute so as to improve perinatal outcome.

The results of this study show that the use of oral terbutaline combined with bed rest was superior to bed rest alone. The mean duration of gestation was prolonged. Although the perinatal mortality could not be compared because of a small sample size, larger numbers should show a positive effect.

The cornerstone for any plan to improve the management of twin pregnancies must be early detection. It is clear that general screening measures are necessary to improve early detection sufficiently to allow any proposed preventative programs to be effective. Once this is accomplished then the use of prophylactic tocolysis is a logical next step.

To date most studies have focused on the role of bed rest. Many reports[1, 3] have suggested benefit in prolonging pregnancy. Because of the logical basis for bed rest with twin pregnancies, it has come into widespread clinical practice and persisted autonomously, requiring no other justification for its use. The use of oral prophylactic tocolysis may allow a further improvement when combined with the use of bed rest.

In summary, the most significant factor in twin mortality is pregnancy termination before the physiologic maturation of the fetus. Almost half of all the infants will weigh <2500 gm, and the use of pharmacologic agents, β-adrenergic drugs, and intravenous alcohol has not consistently been observed to prolong gestation. In this study bed rest and terbutaline have been shown to be associated with higher birth weights in twins compared with those of twins whose mothers had not received the drug. The mechanism for the increased fetal weight is not yet known, but several factors may be operative, such as improved uterine blood flow and possibly increased fetal glucose levels. The concept of bed rest plus tocolysis is attractive because of its simplicity and low cost. The addition of prophylactic terbutaline to bed rest in 28 women was found to be of value in the management of multiple gestations that were otherwise uncomplicated.

Epidemiology of hydatidiform mole during early gestation

Hani K. Atrash, M.D., Carol J. R. Hogue, Ph.D., and David A. Grimes, M.D.
Atlanta, Georgia

Different methodologic approaches have resulted in a wide variability in the reported incidence of hydatidiform mole in the United States. We studied the epidemiology of hydatidiform mole among 84,318 women obtaining legal abortions in the United States during the period 1975 to 1978. Our estimated rate of 7.5 hydatidiform moles per 10,000 pregnancies was similar to most reported rates for the United States. The rate was significantly higher for women 14 years or younger and those 45 years or older. Race, number of previous pregnancies, and number of previous spontaneous abortions were not found to significantly affect the risk of having the disease. The incidence was slightly (but not significantly) higher for women obtaining abortions during the first trimester than for those obtaining abortions during later gestation. This study minimizes the errors encountered in estimating the total number of pregnancies and the number of hydatidiform moles at later stages of gestation. Hydatidiform mole, although relatively uncommon, represents a complication of pregnancy that is of public health importance. (AM J OBSTET GYNECOL 1986;154:906-9.)

Key words: Hydatidiform mole, gestational trophoblastic disease, legal abortion

Hydatidiform mole is an uncommon but important complication of pregnancy. In addition to resulting in the loss of a pregnancy that may be planned and wanted, a hydatidiform mole predisposes a pregnant woman to excessive nausea, vomiting, and malaise.[1] Hydatidiform mole also places a pregnant woman at higher risks of bleeding, pregnancy-induced hypertension, acute pulmonary embolism, and, in rare cases, hyperthyroidism.[2] In 16% of the cases the condition progresses to invasive mole, and in 2.5% it progresses to choriocarcinoma.[2] To prevent the occurrence of the latter two conditions, patients are routinely subjected to repeated laboratory tests, and about 10% of the patients will eventually require chemotherapy.[1]

There has been a wide variability in the reported incidence of hydatidiform mole even within the same country. The reported incidence of hydatidiform mole throughout the world ranges from over 100 per 10,000 pregnancies in Indonesia[3] to 6.9 and 7.7 per 10,000 pregnancies in the United States.[4,5] Within the United States, estimated incidences include 5.8 per 10,000 pregnancies in New York,[6] 9.0 per 10,000 deliveries in California,[7] and 10.8 per 10,000 pregnancies for the United States as a whole.[8] One important reason for this variability in reported incidences is the methodologic approach to assessing the incidence.[9] Part of the problem is the difficulty of assessing the number of women at risk (ideally the number of pregnancies), since that should include live births, still births, ectopic pregnancies, spontaneous abortions, and induced abortions during the study period. Another more important part of the problem is the difficulty in determining the number of cases of hydatidiform mole, since some cases terminate through either spontaneous abortion or induced abortion. Thus a true incidence of hydatidiform mole might more accurately be determined from abortions in early pregnancy.

In this study we review cases of hydatidiform mole among a sample of women undergoing induced abortions in the United States form 1975 to 1978 in an attempt to estimate the incidence of the disease as well as to determine the role of age, race, number of pregnancies, and number of previous spontaneous abortions as risk factors.

Methods

We used information collected by the Joint Program for the Study of Abortion III, a prospective, multicenter, observational cohort study conducted between 1975 and 1978 under the auspices of the Centers for Disease Control to examine early medical complications of legal abortions. This study involved 84,318 abortions performed in 13 institutions. Data were collected by specially trained abstractors at each institution. Information from patients' charts was transcribed onto Joint Program for the Study of Abortion III forms, which were then keypunched and edited. Details of this study have been published.[10]

Cases of hydatidiform mole were identified in two ways: by pathologic examination of the tissue (35 cases) and by operator report of hydatidiform mole as a complication of abortion (28 cases). Fifteen cases identified by both methods were counted only once.

†Significant at $p < 0.05$ level.

The incidence per 10,000 procedures (pregnancies) was calculated for the total study population and for the subgroups. Risk ratios and 95% confidence limits were calculated to compare risks within subgroups. A χ^2 test of significance was calculated to compare the rates obtained in this study with rates estimated by other investigators.

Finally, age- and race-adjusted rates for the pregnant population in the United States were estimated by applying our estimated age- and race-specific rates to the total pregnancies for each subgroup for the study period. Total pregnancies were estimated by adding the number of live births, the reported number of ectopic pregnancies, and the reported number of legal abortions. Spontaneous abortions, which are not reported, were excluded from the number of estimated pregnancies.

Results

Of 84,318 women in the Joint Program for the Study of Abortion III study, 63 were identified as having hydatidiform mole, for an incidence of 7.5 cases per 10,000 pregnancies. The incidence varied with age. The risk of having a hydatidiform mole was lowest for

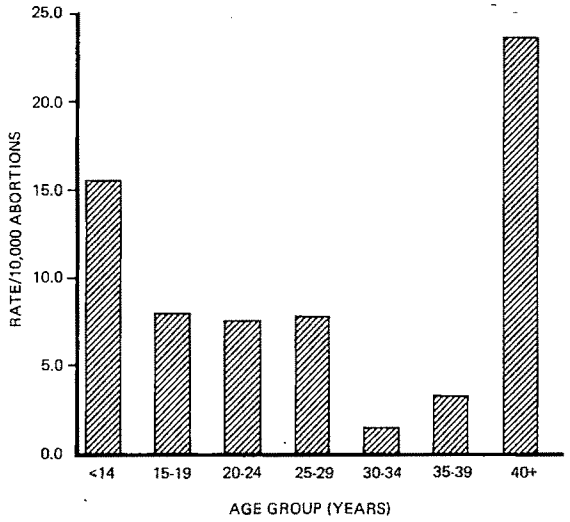

Fig. 1. Hydatidiform mole rate per 10,000 abortions.

women 30 to 34 years of age and highest for women 45 years or older (Table I, Fig. 1). The incidence of hydatidiform mole was highest among Oriental women. However, the difference among the four different racial categories was not significant (Table I).

The age-adjusted rate of 6.9 hydatidiform moles per 10,000 pregnancies and the race-adjusted rate of 7.5 were not significantly different from the crude rate of 7.5 per 10,000 pregnancies.

Women with one or more previous pregnancies had a lower risk of having a hydatidiform mole than women with no previous pregnancies (Table I); this difference was not significant. Women with two or more previous spontaneous abortions had a slightly but not significantly lower risk of having a hydatidiform mole than women who had one or no previous spontaneous abortions (Table I). When stratified by age, the risk did not change significantly with the number of previous pregnancies or the number of previous spontaneous abortions (data not shown).

The rate of hydatidiform mole was higher among abortions done during the first 12 weeks of gestation than among those done at a later gestational age. The rates were not significantly different (Table I).

Our estimated rate was significantly different from the rate estimated by Hayashi et al.,[8] but our estimate was not much different from rates estimated for the United States by other researchers (Table II).

Comment

There are wide variations in the reported incidence of hydatidiform mole from different geographic regions, with higher frequencies generally reported form developing (particularly Oriental) countries. This phenomenon has been explained by some as implying some environmental factor in the etiology of the disease.[7, 11, 12] Within a geographic area, lower socioeconomic status has been an additional factor in some environments[3, 13] but not in others.[4-6, 12] A nutritional factor was hypothesized to explain both the geographic and socioeconomic correlations.[4] The suggestion is that within the United States, even among relatively economically deprived women, the relevant nutritional deficiency is not found.[4] This could explain both the reported lower incidence of hydatidiform mole in the United States and Europe as compared to developing countries and the lack of racial differences found in this and other studies.[6, 11] However, this hypothesis has been tested, and it was repeatedly found that nutrition had no role in the etiology of hydatidiform mole.[4, 6]

Considering race or racial origin to be a separate risk factor associated with hydatidiform mole suggests a hereditary factor. Differences in incidence were reported among populations of different origin in Singapore,[13] Hawaii,[5, 12] California,[7] and Rhode Island.[4] For the United States as a whole, Hayashi et al.[6] found with use of the hospital discharge survey that the incidence of hydatidiform mole among blacks was half that among whites. On the other hand, other studies in Israel[11] and New York[6] reported similar rates for different racial groups. We found that, although the incidence of hydatidiform mole was similar among blacks and whites, it was slightly (but not significantly) elevated for women of Oriental origin.

Probably the only agreed-on risk factor, and the one repeatedly documented as being found, is the increased incidence of hydatidiform mole among teenagers and among women ≥40 years.[4, 7, 8, 11-13] We found a significantly increased incidence for women ≤14 years and for women ≥45 years (Table I, Fig. 1).

Other risk factors for developing hydatidiform mole have been studied, including the number of previous pregnancies, previous spontaneous abortions, and blood groups. However, as is the instance of race, the results are contradictory in most cases.[4, 7] Our study showed no relationship between the incidence of hydatidiform mole and the number of previous pregnancies or the number of previous spontaneous abortions.

In their study of 138 cases of hydatidiform mole in Los Angeles, California, Westerhout et al.[7] noted that, although 75% of all spontaneous abortions would have occurred by the twelfth week of gestation, only about 11% of hydatidiform moles would have terminated by that gestational age. By the twenty-fourth week, 75% of hydatidiform moles would have terminated. Pritchard et al.[2] also report that molar pregnancies terminate from late in the first trimester through the second trimester and that spontaneous expulsion is most likely to occur around the fourth month. Therefore there is some probability that a molar pregnancy will terminate spontaneously before a woman requests a

second-trimester termination procedure. This may be why our reported incidence rates were higher (though not significantly) among abortions done during the first trimester than during the second trimester. This underreporting bias may be an indication that the rate during the first trimester (7.8 per 10,000 pregnancies or 1 per 1280 pregnancies) may be a better estimate of the true rate.

Other factors may have biased our estimate of the incidence of hydatidiform mole. Our study did not eliminate the chance of not counting cases of pregnancies that abort spontaneously at a very early gestational age; we believe, however, that those numbers have been minimized to an extent that they will not significantly affect the numerator (hydatidiform moles) or the denominator (total pregnancies) of our study population.

The number of cases in our study is large enough to estimate with some precision the incidence for the whole population of women obtaining abortions (incidence, 7.5 per 10,000 abortions; 95% confidence limits, 5.8 to 9.6). However, the lack of significant differences among subgroups, particularly when comparing Orientals with women of other races and when comparing women with no previous spontaneous abortions with those with one or more spontaneous abortion, may have resulted from insufficient sample size. The confidence limits around those estimates are quite broad (Table I).

There may be concerns regarding the appropriateness of generalizing our results to the total population of women obtaining abortions in the United States or to the total pregnant population. With respect to the first generalization, the participating clinics, while not a random sample of all clinics, did represent a spectrum of types of facilities and a range of geographic areas.[14] With respect to the second generalization, we know that younger women, older women, and women of races other than white are more likely to have their pregnancies terminated by legal abortion than the rest of the population of pregnant women.[15] Thus we expect those subgroups to be overrepresented in our study group; if one subgroup has a higher risk of having hydatidiform mole (as is the case for younger and older women), our estimated rate may be confounded by that factor. To correct for confounding, we estimated age- and race-adjusted rates. Both adjusted rates were not significantly different from the crude rate.

Ascertainment bias is unlikely to have influenced our estimate. Trained abstractors coded information onto a standard form at the facilities, and an interabstractor reliability study confirmed accurate coding of complications.[10] Misclassification is also unlikely to have occurred, since the diagnosis was made by pathologic examination of the tissue in 35 cases and was based on the operator's report of hydatidiform mole after visual examination of the tissues in the remaining 28 cases.

The pregnant population seeking induced abortion in our study provides an excellent denominator for which a good numerator was obtained by pathologic reports as well as visual examination of tissues. We believe that our study provides a good estimate of the true incidence of hydatidiform mole in early pregnancy.

Assuming that the incidence of hydatidiform mole is 7.5 per 10,000 pregnancies, it is expected that there will be around 3800 women with hydatidiform mole among the approximately 5 million pregnant women in the United States every year.[15, 16] Considering the inconvenience, cost, and risk to which these women are subjected, hydatidiform mole clearly represents a serious public health problem.

Two-dimensional and M-mode echocardiographic findings in hypertensive pregnant women

Ramiro A. Sánchez, M.D., Jorge E. Glenny, M.D., Enrique Marcó, M.D., Liliana S. Voto, M.D., Alicia M. Lapidus, M.D., Guillermo H. Iglesias, M.D., Luis V. Moledo, M.D., and Miguel Margulies, M.D.

Buenos Aires, Argentina

Two-dimensional and M-mode echocardiograms were obtained during the thirty-second week of gestation from 69 women classified as follows: group I, 22 normotensive primigravid women; group II, 16 primigravid women with pregnancy-induced hypertension; group III, 21 pregnant women with essential hypertension; and group IV, 10 normotensive nonpregnant control subjects. Systolic, diastolic, and mean arterial pressures were higher in groups II and III than in groups I and IV ($p < 0.001$). Echocardiographic dimensions were significantly increased in group III compared with the other groups ($p < 0.01$). No significant differences were observed among the other groups in the echocardiographic parameters or in the indices of ventricular performance studied. In echocardiographic studies, chronic hypertensive pregnant women are distinguished from patients with pregnancy-induced hypertension because the former have ventricular hypertrophy resulting from the pressure overload exerted for a long period of time. Our patients with essential hypertension experienced no changes in left ventricular performance because of the early stage of their hypertensive disease. (Am J Obstet Gynecol 1986;154:910-3.)

Key words: Heart, hypertension, pregnancy

From a clinical point of view the natural history of hypertension in pregnancy and its mediate prognosis have not been clearly defined yet. The only means of correlating the clinical and histopathologic findings[1, 2] is through renal biopsy performed within 60 days of delivery. However, since this is an invasive method, it should only be used in selected cases.

Two-dimensional and M-mode echocardiography has proved to be a reliable method to study left ventricular dimensions and function,[3, 4] but so far, echocardiographic studies in normotensive and preeclamptic pregnant women have been performed to assess left ventricular function without focusing on the structural features of the heart.[5, 6] In this study we compared the echocardiographic data obtained from normal, preeclamptic and hypertensive pregnant women in order to obtain a clinical index to differentiate previously hypertensive women from patients with pregnancy-induced hypertension.

Material and methods

Three groups of pregnant women and a nonpregnant control group were included in this study (Table I). Group I consisted of 22 normotensive primigravid women aged 21 to 42 years (mean, 23 years) who had no evidence of any cardiorespiratory disease and whose pregnancies were uncomplicated. Group II comprised 16 pregnancy-induced hypertensive primigravid women aged 16 to 36 years (mean, 26 years) who had no previous history of essential hypertension and whose blood pressure returned to normal after delivery. Hypertension was diagnosed when blood pressure was higher than 140 mm Hg systolic and 90 mm Hg diastolic. Group III consisted of 21 women with essential hypertension whose preexisting elevated blood pressure continued throughout pregnancy and puerperium, as confirmed by 60 days' follow-up after delivery. The age range of these women was 18 to 33 years (mean, 29 years). Finally, a control group, group IV, consisting of 10 normotensive nonpregnant women aged 18 to 27 (mean, 25 years) was also studied.

Table I. Classification of the population studied

Group	*Description*	*n*	*Mean age (yr)*
I	Normotensive primigravid	22	23
II	Pregnancy-induced hypertensive	16	26
III	Essential hypertensive	21	29
IV	Normotensive nonpregnant (control group)	10	25

The echocardiographic studies were performed during the thirty-second week of gestation in all pregnant

Table II. Characteristics of the population studied

	Age (yr)	*Gestational age (wk)*	*Parity*	*Heart rate (bpm)*	*Systolic blood pressure (mm Hg)*	*Diastolic blood pressure (mm Hg)*	*Mean blood pressure (mm Hg)*
Group I—normotensive (n = 22)	23 (21-24)	32	0	98 ± 10	112.18 ± 9	69.73 ± 7	83.98 ± 7
Group II—preeclamptic (n = 16)	26 (16-36)	32	0	102 ± 16	146 ± 11	97.56 ± 7	113.27 ± 9
Group III—essential hypertensive (n = 21)	29 (18-33)	32	0-6	90 ± 13	149.62 ± 13	96.33 ± 9	114.1 ± 9
Group IV—normotensive nonpregnant (n = 10)	25 (19-27)	—	—	74 ± 10	123.3 ± 6	71 ± 6	88.43 ± 4
Group I vs. group II				NS	$p < 0.001$	$p < 0.001$	$p < 0.001$
Group I vs. group III				NS	$p < 0.001$	$p < 0.001$	$p < 0.001$
Group I vs. group IV				$p < 0.01$	NS	NS	NS
Group II vs. group III				NS	NS	NS	NS
Group II vs. group IV				$p < 0.01$	$p < 0.001$	$p < 0.001$	$p < 0.001$
Group III vs. group IV				$p < 0.01$	$p < 0.005$	$p < 0.001$	$p < 0.001$

groups. Blood pressure and heart rate were obtained with the patient in the supine position with use of a Dinamap 845 XT monitor and a 1900 Critikon recorder.

Echocardiographic studies. Two-dimensional and M-mode echocardiograms were obtained with a phased array, wide angle Toshiba System TSH-10A with a 2.25 MHz transducer focused at 7.5 cm, with the patient in either the supine or lateral position. The transducer was placed in the third or fourth intercostal space at the left parasternal border. Measurements were made according to standard techniques.[7, 8] The 11 echocardiographic parameters studied were as follows: end diastolic dimension of left ventricle, end systolic dimension of left ventricle, end diastolic dimension of right ventricle, diastolic interventricular septum, diastolic posterior wall thickness of left ventricle, left atrium, aorta, left ventricular mass, end systolic stress, left ventricular dimension shortening, and end systolic stress/end systolic volume index.

The technique of Devareux and Reichek[9] was used to measure left ventricular mass (LVM):

$$LVM = 1.04\,[(EDDp + DIVSp + DPWTp)^3 - (EDDp)^3] - 13.6$$

where p indicates modified (Penn) convention for determining EDD (end-diastolic dimension of the left ventricle), DIVS (diastolic interventricular septum), and DPWT (diastolic posterior wall thickness of the left ventricle).

To determine end-systolic stress (ESS), the method of Wilson et al.[10] was used:

$$ESS = \frac{0.334 \times SBP \times ESD}{SPWT \times (1 + SPWT/ESD)}$$

where ESD = end-systolic diameter of the left ventricle, SBP = systolic blood pressure when echocardiograms were recorded, and SPWT = systolic posterior wall thickness of the left ventricle.

Percentage fractional shortening (PFS) was determined as follows[11, 12]:

$$PFS = \frac{EDD - ESD}{EDD} \times 100$$

and PFS and ESS/ESVI (end-systolic stress/end-systolic volume index ratio) were used as the ventricular index.[13] The method of Teicholz et al.[14] was used to determine end-systolic volume (ESV).

Statistical study. All data are expressed as mean ± standard deviation. Statistical significance was calculated by the analysis of variance.

Results

Systolic, diastolic, and mean blood pressures were significantly higher in patients with preeclampsia and essential hypertension than in the other groups ($p < 0.001$). However, no differences were found between the essential hypertensive and preeclamptic patients. Preeclamptic, normotensive, and essential hypertensive pregnant patients showed a higher heart rate than the nonpregnant control women (Table II).

Echocardiographic measurements. When compared with the other groups, patients with essential hypertension had a significant increase in EDD, DIVS, DPWT, and LVM. With regard to aorta dimensions, only a slight difference was observed between essential hypertensive and normotensive pregnant women. No significant differences were observed among the normotensive, preeclamptic, and control women, with the exception of left ventricular mass, which was greater in the preeclamptic women than in the control group.

In contrast with these observations, the ESD of the right ventricle, as well as ESS were similar in all groups.

Table III. Results of the study

	End diastolic dimension of left ventricle (mm)	*End systolic dimension of left ventricle (mm)*	*End diastolic dimension of right ventricle (mm)*	*Diastolic interventricular septum (mm)*
Group I—normotensive (n = 22)	46.9 ± 4	29.23 ± 5	16.0 ± 6	8.64 ± 1
Group II—preeclamptic (n = 16)	47.31 ± 3	30 ± 4	17.1 ± 5	9 ± 1
Group III—essential hypertensive (n = 21)	49.81 ± 4	30.75 ± 4	17.4 ± 4	9.95 ± 2
Group IV—normotensive nonpregnant (n = 10)	45.6 ± 2	28.9 ± 2	16.6 ± 2	7.1 ± 1
Group I vs. group II	NS	NS	NS	NS
Group I vs. group III	$p < 0.01$	NS	NS	$p < 0.01$
Group I vs. group IV	NS	NS	NS	NS
Group II vs. group III	$p < 0.05$	NS	NS	$p < 0.05$
Group II vs. group IV	NS	NS	NS	NS
Group III vs. group IV	$p < 0.05$	NS	NS	$p < 0.01$

LVM increased significantly in essential hypertensive women, compared with the other groups. Left PFS and the ESS/ESV ratio index, as an expression of ventricular systolic performance, were normal in the groups with preeclampsia and essential hypertension; furthermore, no significant differences were found among the groups (Table III). There was no echocardiographic evidence of left ventricular diastolic dysfunction in any of the groups.

Comment

The physiologic changes observed during pregnancy, such as the increase in maternal metabolic requirements, the decrease in peripheral vascular resistance and the increase in blood volume, cause significant changes in cardiac output during pregnancy as early as the thirteenth week of gestation,[15, 16] as evidenced by the increase in cardiac output and systolic volume.[15, 16]

Rubler et al.[15] performed echocardiographic studies in normotensive patients. These results showed a progressive increase in left and right ventricular dimensions from the thirteenth week of gestation on. These observations demonstrate that these physiologic changes appear concomitantly with the necessary increase in cardiac output to compensate for the augmented metabolic requirements during gestation. The echocardiographic data obtained from our population of normotensive pregnant women at the thirty-second week of gestation are in agreement with the findings reported by Rubler et al.[15] The results obtained by other investigators on the left ventricular systolic function in patients with pregnancy-induced hypertension vary widely; Kuzniar et al.[6] found a reduced cardiac output and ESV in preeclampsia. However, no differences between normotensive and hypertensive women were found by Assali et al.[17] We found that at the thirty-second week of gestation, ventricular systolic performance was normal in all the groups studied. This difference in results among some papers may be due to the methods used and/or the selection of the population. In our study echocardiograms have shown significant differences in cardiac structures. Thus essential hypertensive patients showed a significant increase in left ventricular PWT, interventricular septum, LVM, and EDD of the left ventricle. In contrast, left ventricular dimensions remained unchanged in preeclampsia, since hypertension only lasts the course of gestation and blood pressure may not be excessively high, as found in this study. In essential hypertension, left ventricular hypertrophy as well as a slight increase in EDD of the left ventricle occur in order to preserve left ventricular systolic function and compensate for the pressure effect and volume load of the heart. Only pregnant women with essential hypertension showed echocardiographic structural differences, although ventricular systolic function was normal, which may indicate that these patients are in an early stage of the development of hypertension.

Our study showed that echocardiographic changes were only observed in pregnant women with essential hypertension. Thus we propose the use of echocardiography as another parameter in the differentiation of pregnancy-induced hypertension from essential hypertension in pregnant women.

Sodium excretion in human pregnancy: A role for arginine vasopressin

Mark A. Brown, M.B., B.S.,* and Eileen D. M. Gallery, M.D.
Sydney, Australia

Plasma arginine vasopressin concentration was measured before and after 1 week's dietary sodium loading (>250 mmol/day) or deprivation (<50 mmol/day) in 50 second-trimester and 34 third-trimester primigravidas. A significant rise in plasma arginine vasopressin was observed only in second-trimester subjects following sodium loading (5.6 ± 0.5 to 6.6 ± 0.5 pg/ml; $p < 0.05$). Plasma sodium concentration and blood pressure did not alter, and plasma volume increased slightly in this group (24.4 ± 0.5 to 25.9 ± 0.7 ml/cm height; $p < 0.01$). Hence the observed increment in plasma arginine vasopressin concentration in this group could not be explained by alterations to the major factors regulating arginine vasopressin release. It is suggested that arginine vasopressin secretion increases to assist natriuresis following dietary sodium loading in the second trimester of human pregnancy. (Am J Obstet Gynecol 1986;154:914-9.)

Key words: Arginine vasopressin, natriuresis, plasma volume

The regulation of sodium excretion in human pregnancy remains poorly understood. Although there is a net sodium retention of approximately 3 mmol/day,[1] the mechanisms determining this final sodium balance are unclear. Several hormones, including aldosterone, deoxycorticosterone acetate, and progesterone, are known to play a considerable role in the control of sodium excretion, but the role of other hormones is less clear.

Although a role has been described for arginine vasopressin in sodium regulation in man and other mammals, the effects of arginine vasopressin on sodium excretion in pregnancy are uncertain. The only two studies that have addressed this question in human pregnancy have produced conflicting results, one noting a considerable sodium-retaining effect[2] and the other demonstrating a marked natriuretic effect of this hormone.[3] A sodium-retaining action of this hormone might contribute to the salt and water retention that is characteristic of normal pregnancy and enhanced in many cases of established pregnancy-associated hypertension (preeclampsia).[4]

Conversely, if the predominant effect of arginine vasopressin on sodium is to enhance its excretion during pregnancy, then the result might be relative contraction of the plasma volume from its normally expanded state, which is characteristic of pregnancy-associated hypertension.[5]

Understanding the effects of arginine vasopressin on sodium excretion in humans has been complicated by the need to extrapolate data from animal studies or from studies utilizing exogenous infusions of arginine vasopressin. The latter pose the particular difficulty of relating the effects of arginine vasopressin infusions to actual physiologic events. However, the development of sensitive and specific radioimmunoassays for the measurement of plasma arginine vasopressin has already provided new concepts of the physiology of this hormone in human pregnancy[6] and might provide insights into its proposed role in regulating sodium excretion.

If arginine vasopressin is indeed a sodium-regulatory hormone in human pregnancy, then it could be expected that endogenous plasma arginine vasopressin concentrations alter in response to changes in dietary sodium intake to restore sodium balance. However, other factors, such as plasma osmolality, blood pressure, and plasma volume, are the major known determinants of arginine vasopressin secretion,[7] and these factors might also be influenced by an alteration in sodium intake.

Therefore we monitored these factors together with plasma arginine vasopressin concentrations before and after dietary sodium loading or deprivation during the second and third trimesters of human pregnancy in order to seek evidence for a role for this hormone in regulating sodium excretion.

Material and methods

Clinical studies. Eighty-four studies were made in 58 primigravidas who remained normotensive through-

out their pregnancy. All were participants in a large prospective study of sodium control in pregnancy and had no prior history of hypertension or of renal or cardiac disease. After giving written informed consent, subjects were assigned randomly to either a high-salt or low-salt diet, which was taken for 1 week during the second trimester (22 to 26 weeks' amenorrhea) or third trimester (32 to 36 weeks' amenorrhea). Thirteen subjects in each dietary group had studies during both trimesters.

The high-salt diet consisted of a food intake with approximately 150 mmol of sodium/day supplemented by sodium chloride capsules (17 mmol sodium/capsule) to a total intake of approximately 300 mmol/day, the dietary aim being a sodium intake of ≥250 mmol/day. Those subjects undertaking a low-salt diet were instructed in a dietary sodium intake of approximately 20 mmol/day, the dietary aim being a sodium intake of <50 mmol/day. All subjects collected urine for 48 hours before the commencement of their diet and for the last 48 hours of their diet, for measurement of urine volume and of sodium and creatinine excretion. At the commencement (day 0) and completion (day 7) of the diet, subjects attended a special clinic between 7:00 and 10:00 AM, where blood was collected for the measurement of plasma sodium concentration, plasma arginine vasopressin concentration, plasma renin activity, and plasma aldosterone concentration, and plasma volume was measured. On these same days the blood pressure was measured after 10 minutes' rest, with the patient in the sitting position. Diastolic blood pressure was recorded at the phase IV Korotkoff sound with the use of a Hawkesly random zero sphygmomanometer.

Analytical methods

Collection and handling procedures. For measurement of plasma arginine vasopressin concentration, 10 ml of blood was placed immediately into tubes that had been prechilled in ice and that contained disodium ethylenediaminetetra-acetic acid (Na_2 EDTA). After centrifugation in the cold, plasma was separated and extracted within 3 hours. Five milliliters of blood was also drawn into a tube containing Na_2 EDTA and handled at room temperature before snap freezing for later determination of plasma renin activity and plasma aldosterone concentration. A further 20 ml of blood was collected for measurement of the biochemical profile, including plasma sodium concentration, and as a "blank" sample for determination of the plasma volume.

Laboratory methods. Plasma arginine vasopressin was measured by a modification of the method of Woods.[8] The addition of phenanthroline monohydrate caused significant displacement of the standard curve and prevented its use as an inhibitor of the vasopressinases. Cold and Na_2 EDTA were used as inhibitors, and the extraction was performed in ice slush with Na_2 EDTA added to the buffer. Plasma was extracted with the use of acetone and petroleum ether, and recovery of added synthetic arginine vasopressin was consistently 65% to 70% in nonpregnant subjects and in both second- and third-trimester subjects. Standard curves were prepared in duplicate over a range of 0.5 to 125 pg arginine vasopressin per tube by means of the international standard for arginine vasopressin.* Iodinated arginine vasopressin,† with a specific activity of 2200 μCi/μmol, was incubated with standard arginine vasopressin and with arginine vasopressin antibody for 24 hours at room temperature. The antibody, prepared in rabbits, has a 10% cross-reactivity with lysine vasopressin and less than 1% cross-reactivity with oxytocin. Separation of bound and free arginine vasopressin was achieved with a solid-phase second antibody-coated cellulose suspension (Sac-cel),‡ and bound arginine vasopressin radioactivity was counted by gamma counting for 4 minutes per tube. Results were not corrected for recovery and are expressed as picograms of arginine vasopressin per milliliter of plasma.

Assay sensitivity was 1.3 pg/ml, the intra-assay coefficient of variation was 9.4 ± 0.9% (n = 20 assays), and the interassay coefficient of variation was 13.4 ± 1.0% (n = 9 assays). The 50% displacement value was 7.9 pg/ml. Under conditions of normal hydration and eating without restriction, the mean plasma arginine vasopressin concentration was 5.1 ± 0.4 pg/ml in 20 healthy nonpregnant volunteers and 5.1 ± 0.2 pg/ml in 49 primigravid pregnant women studied at a mean gestation of 29 ± 0.4 weeks.

Plasma renin activity was measured by radioimmu-

noassay of angiotensin I with care to avoid cryoactivation.[9] Plasma aldosterone concentration was measured by radioimmunoassay, plasma sodium concentration by the AutoAnalyzer method, and plasma volume by an Evans blue dye–dilution technique as previously described.[5]

Urine sodium was measured by flame photometry,* and urine creatinine was determined spectrophotometrically after colorimetric reaction with alkaline picrate. Results for urine sodium excretion were then expressed both as millimoles per day and as millimoles of sodium excreted per millimole of creatinine excreted (Na:Cr ratio) from the 2-day urine collections, the latter method being used as a check for adequacy of urine collections.

Statistical analysis. Within-patient differences were analyzed by paired Student's *t* test and differences between groups by unpaired Student's *t* test. Correlations were evaluated by determination of the Pearson correlation coefficient. Results are expressed as the mean ± SEM.

Results

Subjects. During the second trimester, studies were made in 23 subjects in the high-salt group and 27 subjects in the low-salt group (Table I). In the third trimester the same studies were made in 16 subjects undertaking a high-salt diet and in 18 subjects using a low-salt diet. Thirteen subjects in each dietary group had studies made during both trimesters. Results in these subjects did not differ from those in the larger groups from which they arose. There was no significant difference between dietary groups in age, height, or stage of gestation.

Urinary sodium excretion. There was no significant difference in baseline (day 0) urinary sodium excretion or urine Na:Cr ratio between dietary groups in the second or third trimesters (Table II). The urinary sodium excretion rose significantly ($p < 0.001$) following a high-salt diet and fell significantly ($p < 0.001$) following a low-salt diet in both trimesters. The same pattern of changes was observed for urine Na:Cr ratios.

Plasma arginine vasopressin concentrations. Plasma arginine vasopressin concentration rose significantly ($p < 0.05$) following a high-salt diet in second-trimester subjects but not in third-trimester subjects eating this same diet (Fig. 1). No significant change in plasma arginine vasopressin concentration was observed after a low-salt diet in either trimester.

Factors regulating plasma arginine vasopressin concentration and sodium excretion. Plasma sodium concentration was altered only in the low-salt group during the second trimester (Table III). This change was accompanied by a small but significant fall in the plasma volume (0.9 ml/cm; $p < 0.05$). The plasma volume increased slightly but significantly in the high-salt groups during both trimesters and remained constant in the low-salt group during the third trimester.

Blood pressure was not significantly influenced by any dietary manipulation, but plasma renin activity and plasma aldosterone concentration rose significantly in both low-salt groups and fell significantly in both high-salt groups.

Data were further analyzed within the second-trimester high-salt group, where an increase in mean plasma arginine vasopressin concentration was observed. Changes in plasma arginine vasopressin concentrations for each subject were analyzed with the corresponding changes in plasma renin activity, urine sodium excretion, and diastolic blood pressure, but no significant correlations between arginine vasopressin concentrations and these parameters were observed.

Comment

We have found an increase in plasma arginine vasopressin concentration in response to dietary sodium loading in the second trimester of human pregnancy. No change in blood pressure or plasma sodium concentration occurred with this maneuver, and the increment in plasma volume should, if anything, have resulted in a marginal fall in arginine vasopressin secretion.[10] Therefore some other factor must have provided

the stimulus for the observed increase in plasma arginine vasopressin concentration in this group.

The major determinants of arginine vasopressin release have been reviewed by Robertson.[10] In addition to osmotic, volume, and blood pressure stimuli, only nausea appears to be capable of significantly influencing arginine vasopressin release in nonpregnant subjects. Further, changes in plasma sodium concentration appear necessary to exert any osmotic influence on arginine vasopressin release, and infusions of glucose, although increasing plasma osmolality, do not increase arginine vasopressin secretion.[11] None of our patients complained of nausea at the time of their study, and the plasma sodium concentration did not rise significantly in any subject. Other stimuli, such as angiotensin II and hypoglycemia, appear to be very weak in their ability to elicit arginine vasopressin release and are not thought to be of clinical importance in disorders of water balance.[10] Plasma renin activity, and presumably then angiotensin II, fell in our high-salt group, which

demonstrated a rise in plasma arginine vasopressin concentration, and none of these subjects developed hypoglycemia. Thus the major known stimuli for the release of arginine vasopressin cannot explain the increment in this hormone that we observed to be a response to sodium loading in the second trimester. The observed rise in endogenous plasma arginine vasopressin concentration may therefore represent an attempt to enhance renal sodium excretion by this hormone, as suggested previously for pregnant women.[3] This possibility is supported by the finding that plasma arginine vasopressin concentration rises significantly in at least one other group, nonpregnant patients with essential hypertension, following a 250 mmol/day sodium intake.[12] Although significant changes in the plasma volume were observed following alterations in sodium intake in this study, these changes were small. This constancy of plasma volume has no doubt been mediated partly by appropriate changes in the renin-aldosterone system, but it is also possible that arginine vasopressin assisted the natriuresis following sodium loading in the second trimester. However, the understanding of arginine vasopressin in relation to sodium excretion is limited. Some studies have demonstrated natriuretic effects of this hormone,[13] although the infusion doses of arginine vasopressin have sometimes been sufficiently high to elicit a pressor response and thereby secondarily promote natriuresis. Similarly, overhydration per se is capable of promoting natriuresis, and many studies, in an attempt to suppress endogenous arginine vasopressin production, have utilized this procedure. Recently, Field et al.[14] studied the effects of arginine vasopressin infusions in Brattleboro rats (who produced no endogenous arginine vasopressin) and were unable to demonstrate any role for arginine vasopressin in regulating sodium excretion. Conversely, others have claimed that arginine vasopressin promotes sodium retention perhaps in the ascending limb of Henle's loop.[15] No similar studies appear to have been performed in pregnant animals.

In man, arginine vasopressin is thought to promote fractional sodium reabsorption, urea reabsorption, and potassium excretion.[16] In two studies of the effects of arginine vasopressin in human pregnancy, sodium excretion has been found to fall and increase. In the former study,[2] large doses of Pitressin were administered, and the consequent reduction in glomerular filtration rate was the most likely explanation for the decreased urine sodium excretion. Calculation of the fractional sodium excretion in these subjects shows that tubular sodium reabsorption was variably altered, in some cases increasing. In contrast, Torres el al.[3] infused very small doses of arginine vasopressin and found a doubling of the fractional sodium excretion in second-trimester subjects but only a minimal increase in third-trimester subjects. Our data regarding endogenous arginine vasopressin concentrations are consistent with these latter findings and suggest a natriuretic effect of arginine vasopressin, operative in second-trimester but not third-trimester pregnant women following dietary sodium loading. Recent evidence suggests that a fall in plasma arginine vasopressin concentration following dietary sodium deprivation would not be expected, since arginine vasopressin appears important in the regulation of sodium excretion only when the body is loaded with sodium.[17] This finding is supported by the absence of a fall in plasma arginine vasopressin concentration after a low sodium intake by the pregnant women studied here. Although arginine vasopressin may enhance sodium excretion, we have shown that it is not regulated by the body's sodium status in a manner similar to other primary sodium-regulating hormones such as aldosterone, which we confirmed to rise and fall appropriately in our subjects following dietary sodium manipulation.

In attempting to explain the mechanism for arginine vasopressin–assisted natriuresis, we examined the relationship between changes in arginine vasopressin concentration and changes in plasma renin activity in second-trimester sodium-loaded subjects, since arginine vasopressin is capable of suppressing renin release.[18] No significant correlation between these two parameters was observed in this study, making it unlikely that the natriuretic effect of arginine vasopressin is mediated by renin suppression.

This study is the first to monitor endogenous plasma arginine vasopressin levels in human pregnant subjects in response to dietary sodium loading. The findings support previous suggestions[3] that arginine vasopressin plays a role in sodium excretion in the second trimester of pregnancy. If this hormone is involved in the pathogenesis of the hypertensive disorders of pregnancy, then its actions might explain both the contracted plasma volume and the increased total body water that may accompany these disorders. Further examination of the role of arginine vasopressin and its relationship to sodium excretion and water balance in both pregnancy-associated hypertension and chronic hypertension in pregnancy will elucidate its significance in their pathogenesis.

We thank the obstetricians of the Royal North Shore Hospital, Sydney, for allowing us to study their patients, Prof. A.Z. Gyory for advice and discussion, and Sister Margaret Ross, Dr. Georgina Crawford, Mrs. Ellen Nicholson, and Miss Helen Norton for their expert technical assistance.

Profound hypotension complicating magnesium therapy

F. John Bourgeois, M.D., Siva Thiagarajah, M.D., Guy M. Harbert, Jr., M.D., and Cosmo DiFazio, M.D.
Charlottesville, Virginia

Two preeclamptic women became profoundly hypotensive while receiving magnesium sulfate. No evidence of toxic levels was present in either. In both, preeclampsia-induced hypovolemia was extreme. That nontoxic magnesium levels can cause severe hypotension is an alarming possibility. Acknowledgment of this complication and expeditious reversal of the problem is essential. (AM J OBSTET GYNECOL 1986;154:919-20.)

Key words: Preeclampsia, magnesium sulfate, hypotension

Magnesium sulfate administered at accepted therapeutic doses for preeclampsia influences blood pressure slightly.[1] Significant hypotension is not a generally recognized side effect. Two preeclamptic women treated with a well-established dosage schedule[2] designed to produce serum magnesium levels of 6 to 8 mEq/L became severely hypotensive. They did not have toxic magnesium levels, and their response to the drug is in contrast to a large number of preeclamptic patients receiving the drug according to the same protocol.

Case reports

Case 1. A primigravid woman presented to an outlying hospital at 35 weeks' gestation with edema, proteinuria, and blood pressure of 180/120 mm Hg. After 3 hours of intravenous magnesium sulfate administration (total dose of 6 gm), the blood pressure dropped to 64/40 mm Hg. Magnesium was discontinued, and blood pressure rose to 160/98 mm Hg within 15 minutes. Pulse remained 70 bpm throughout.

After transfer the blood pressure was 210/136 mm Hg and pulse was 104 bpm. Laboratory studies were normal except for serum albumin level of 2.5 gm/dl.

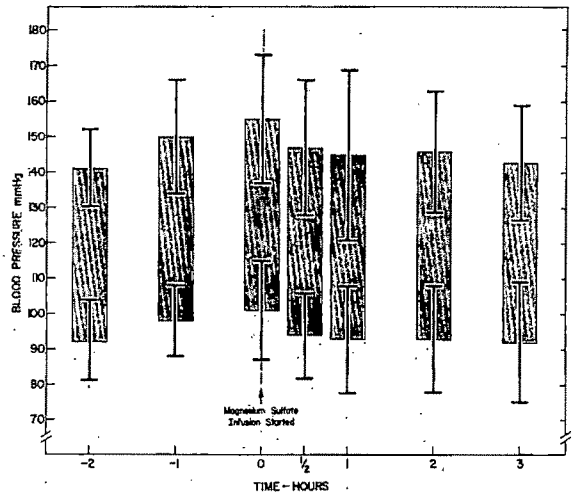

Fig. 1. Systolic, diastolic, and mean arterial pressure changes in 320 preeclamptic women treated with magnesium sulfate.

Serum calcium level was 7.6 mg/dl and magnesium level was 4.1 mEq/L.

Magnesium sulfate was administered intravenously by calibrated infusion pump at a rate calculated to deliver 8400 mg in the first hour. Within 20 minutes blood pressure was 70/50 mm Hg, and the infusion was discontinued. Blood pressure returned promptly to hypertensive levels. Serum magnesium level drawn minutes after the hypotensive episode was 4.5 mEq/L. The patient then received 1500 ml of intravenous normal saline solution, raising the central venous pressure from 0 to 7. A healthy 1990 gm infant was delivered and the patient became normotensive after delivering.

Case 2. A woman, gravida 2, para 1, with twin gestation, presented to another hospital at 31 weeks with headache, epigastric pain, blood pressure of 160/110 mm Hg, and proteinuria. Before transfer, magnesium sulfate, 10 gm, was given intramuscularly.

On arrival, blood pressure was 178/100 mm Hg and deep tendon reflexes were 3+. Laboratory studies were normal except for albumin of 3.0 gm/dl. Serum magnesium was not measured; calcium level was 8.2 mg/dl. Magnesium sulfate was infused as described previously. This was begun 2 hours after the single intramuscular dose mentioned. Within 15 minutes during which 2100 mg of magnesium sulfate was administered by calibrated pump, blood pressure was 70/50 mm Hg. The infusion was discontinued, and blood pressure rose to 150/94 mm Hg in <10 minutes. Urine output decreased to 25 ml/hour, and central venous pressure was measured at 2. Plasma protein was given slowly, raising the central venous pressure to 7.

Subsequently the patient delivered healthy 2110 and 1410 gm infants. Hypertension resolved slowly after delivery.

Both women received 25 mg of intravenous promethazine along with the magnesium infusion, but neither received any other medication. Both patients were placed in semirecumbent position. Neither had depressed respirations or deep tendon reflexes.

Blood pressure response to magnesium is usually slight in eclamptic patients.[1] An illustration of the blood pressure changes in 320 preeclamptic women given magnesium sulfate infusion according to the regimen of Hall[2] (Fig. 1) demonstrates only a modest mean decrease. In 26 years, with use of this protocol for magnesium administration, no similar instances of hypotension have been recognized. There is no evidence of toxic magnesium levels in these patients, and other women receiving both magnesium and promethazine demonstrated no such blood pressure change. The severe degree of hypovolemia probably combined with magnesium-induced vasodilatation to produce this condition.

Electrocardiographic changes associated with ritodrine-induced maternal tachycardia and hypokalemia

Susan K. Hendricks, M.D., Jonathan Keroes, M.D., and Michael Katz, M.D.
San Francisco, California

One hundred twelve patients in preterm labor were followed prospectively, with electrocardiograms taken before ritodrine therapy and at 6 and 24 hours of treatment. Ninety-six percent of patients developed sinus tachycardia. Other changes were seen in 79% of the study group. These changes included ST segment depression in 70%, T wave flattening or inversion in 55%, and prolongation of the QT interval in 35% of our sample. None of the electrocardiograms showed the presence of a significant axis deviation, a change in QRS interval, or arrhythmia. No correlation was seen between symptoms of ischemia and electrocardiographic changes. A drop in potassium concentration was noted initially, but a direct correlation between potassium concentrations and frequency of electrocardiographic changes was not present. We conclude that the electrocardiographic changes that are often observed during myocardial ischemia may be frequent in asymptomatic patients treated with ritodrine and that these changes may be a physiologic expression of ritodrine-induced tachycardia or hypokalemia. The validity of the use of the presence of electrocardiographic changes as the only criterion for discontinuation of ritodrine therapy is questioned. (AM J OBSTET GYNECOL 1986;154:521-3.)

Key words: Electrocardiography, ritodrine

Since the approval by the Food and Drug Administration of ritodrine as a tocolytic agent, widespread usage has evolved. Past experience with β-adrenergic tocolytics has shown the occurrence of severe cardiovascular complications including pulmonary edema, myocardial ischemia, and myocardial infarction in up to 5% of patients treated parenterally.[1-3] In addition, minor side effects such as nausea, vomiting, palpitations, nervousness, and tremulousness occur at frequencies of up to 30%.[3] Following these reports, most practitioners perform electrocardiographic studies in the presence of chest discomfort or shortness of breath, although some perform these tests routinely. Based on electrocardiographic changes consistent with myocardial ischemia, therapy is often discontinued.[4] However, since the frequency of electrocardiographic changes in asymptomatic patients undergoing ritodrine tocolysis has not been previously established, their specificity as well as relationship to myocardial stress are not clear. Therefore the clinical value of electrocardiograms in the management of these patients has remained unknown.

The following report represents an analysis of electrocardiographic changes associated with ritodrine therapy. Our goal was to identify and characterize these changes during tocolysis and to ascertain whether their presence could be correlated with significant clinical symptoms.

From the Departments of Obstetrics, Gynecology, Reproductive Sciences, and Cardiology, Children's Hospital and the University of California, San Francisco.
Received for publication August 23, 1985; revised December 6, 1985; accepted December 12, 1985.

Materials and methods

One hundred twelve consecutive patients diagnosed as having preterm labor between 26 and 34 weeks' gestation underwent electrocardiography before initiation of tocolysis. The diagnosis of preterm labor was made in the presence of regular uterine contractions leading to cervical change. All patients had normal intake electrocardiograms and no cardiovascular risk factors such as hypertension, cardiac arrhythmias, or angina in their medical histories. The electrocardiograms were repeated at 6 hours of therapy in all patients and again at 24 hours in those patients still receiving intravenous ritodrine therapy. Our ritodrine infusion protocol required meticulous monitoring of fluid administration and vital signs. Fluid intake was limited to 1.8 L/24 hr, since previous reports have shown fluid overload to be the critical factor in development of pulmonary edema.[1, 3, 5] Our ritodrine infusion protocol is as follows:

1. 300 mg of ritodrine per 500 ml of normal saline solution = 600 μg ritodrine per milliliter.
2. Initial ritodrine infusion rate: 100 μg/minute; increase dose 50 μg/minute every 10 to 15 minutes.
3. Monitor vital signs every 10 to 15 minutes.
4. Avoid the following: pulse >120 bpm, systolic pressure <90 torr, diastolic pressure <40 torr.

Table I. Serum potassium ion concentrations after 6 hours of ritodrine infusion in relationship to the frequencies of electrocardiographic abnormalities*

Potassium concentration at 6 hours (mEq/L)	*Normal (%)*	*ST (%)*	*T wave (%)*	*QTc (%)*
>3.5	7	22	13	7
3.0-3.5	13	26	18	7
2.5-2.9	11	7	13	0
<2.5	9	7	0	7

*All patients had initial potassium concentration >3.5 mEq/L.

5. Limit total fluid intake to ≤75 ml/hr.

6. Obtain electrocardiogram, serum electrolytes test, and complete blood count before therapy and at 6 hours.

The electrocardiograms were reviewed by a cardiology specialist. The variables that were evaluated in each electrocardiogram were heart rate (sinus tachycardia = >100 bpm), rhythm, presence of ST depression (>1 mm), T wave inversion or flattening, QRS intervals, axis shifts, and QT intervals.

Results

Two of the 112 patients treated with ritodrine developed serious cardiovascular symptoms during the course of therapy. Both patients experienced significant angina, and one ultimately developed pulmonary edema attributed to a moderate fluid overload, received through excessive intravenous therapy despite a protocol setting rigid limitations for fluid administration. Neither of these patients had an abnormal electrocardiogram.

Ninety-six percent of the patients developed sinus tachycardia during ritodrine therapy. Other electrocardiographic changes occurred in 79% of the study group. These changes included ST segment depression in 70%, T wave flattening or inversion in 55%, and prolongation of the QT interval, corrected for rate, in 35% of our sample. None of the electrocardiograms showed a significant axis deviation, a change in QRS interval, or arrhythmia.

Seventy-six percent of the patients had either ST segment changes, T wave changes, or both. These changes were primarily seen in the inferolateral leads—II, III, AVF, and V3 to V6—the area primarily supplied by the right coronary artery.

The electrocardiographic changes after 24 hours of intravenous therapy demonstrated a persistent, though less marked, sinus tachycardia. Eighty-nine percent of these electrocardiograms showed a return trend toward the baseline pretreatment electrocardiograms. There was a noted resolution of ST-T wave changes toward an isoelectric baseline.

No statistical correlation could be drawn between the rate of ritodrine administration and the incidence of electrocardiographic changes in our population. Serum concentrations of ritodrine or β-receptor activity might be of value in future investigations.

Potassium levels drawn before therapy and every 6 hours thereafter showed a resolution toward pretreatment levels without potassium supplementation. There was no relationship between serum potassium concentrations and electrocardiographic changes (Table I).

Comment

β-Adrenergic stimulators are not as specific in vivo as they are in vitro, and therefore both β_2 and β_1 receptors are stimulated by the tocolytics that are presently in clinical use. This incomplete in vivo affinity results in multiple major and minor adverse side effects.

Myocardial ischemia in symptomatic patients has been reported by several authors[1, 3, 4, 6] and electrocardiographic changes in one asymptomatic patient were reported by Michalak et al.[7] Based on these reports of maternal cardiovascular morbidity and even mortality, many practitioners have chosen to evaluate all symptomatic patients with electrocardiograms. The results of these evaluations have been used as criteria to continue or discontinue tocolytic therapy.[8] Specifically, ST segment depression and T wave flattening or inversion could be considered indicative of myocardial dysfunction necessitating cessation of treatment. However, the frequency of electrocardiographic changes in asymptomatic patients undergoing tocolytic therapy has not been previously established for ritodrine. With use of a different β-adrenergic agent, German investigators[9] noted similar findings to those described by us in this study. Wiest et al.[9] showed that ST segment depression and T wave flattening or inversion were present in a majority of women treated with fenoterol for preterm labor. Furthermore, the same authors reported that serum concentrations of serum glutamic oxaloacetic transaminase and lactate dehydrogenase in those women who had electrocardiographic changes were normal and thus probably not representing a significant myocardial damage.[9] In other reports, measurements of the MB isoenzyme fraction of creatinine phosphokinase in patients with electrocardiographic changes have shown no elevations.[10, 11]

In this study we have shown that a majority of women undergoing ritodrine therapy did develop electrocardiographic changes that suggested myocardial ischemia, but they remained asymptomatic. Therefore no obvious relationship between symptoms of myocardial ischemia and electrocardiographic changes could be established. The physiologic significance of these changes could be explained by a maternal adaptation to the

ritodrine-induced tachycardia. Relative hypoperfusion of the subendocardium may cause subtle changes in the maternal electrocardiograms even in the absence of functional ischemia and enzyme abnormalities. The normal 1:1 perfusion ratio of epicardium to subendocardium may be altered by heart rate changes. Development of a sinus tachycardia is often accompanied by a relative decrease in blood flow to the subendocardium.[6] This is considered a physiologic adaptation, which has also been noted to occur during exercise-induced tachycardia and has no known pathologic significance. However, this rate-induced change in myocardial perfusion ratio has never been associated with changes in more sensitive indicators of myocardial damage such as serum cardiac enzyme elevations.[9]

Ritodrine-induced hypokalemia evolves from movement of potassium into the intracellular space.[8, 12, 13] Numerous investigators have shown that the serum potassium level drops sharply in the first 6 to 8 hours of therapy without an increase in urinary potassium excretion.[8, 12, 13] However, potassium concentration returns toward normal without supplementation by 24 hours of therapy.[8, 12, 13] Since the electrocardiographic changes seen in this study were not associated directly with degree of hypokalemia, a relationship between serum potassium concentration and the presence of electrocardiographic changes could not be established.

In conclusion, our study has shown that electrocardiographic changes in a sample of patients undergoing ritodrine therapy may be a frequent event. No relationship between symptoms of ischemia and electrocardiographic changes could be seen. We suggest that these changes could be physiologic expressions of ritodrine-induced maternal tachycardia and are not likely to be representative of myocardial ischemia. Based on our present data, we doubt the validity of the use of electrocardiograms of asymptomatic patients as a sole criterion for discontinuation of β-adrenergic therapy. Additional cardiovascular evaluations such as echocardiograms and serum cardiac enzyme concentration tests are necessary to establish the true significance of the electrocardiographic changes in the asymptomatic patient.

Ritodrine-induced neutropenia

Rebekah Wang-Cheng, M.D., and Bert J. Davidson, M.D., Ph.D.
Loma Linda, California

Ritodrine hydrochloride, a β-sympathomimetic treatment for premature labor, has been associated with the development of pulmonary edema, various metabolic derangements, myocardial ischemia, and infarction. We present the first reported case of absolute neutropenia after prolonged intravenous administration of ritodrine with rapid, spontaneous reversal once the medication was discontinued. (Am J Obstet Gynecol 1986;154:924-5.)

Key words: Ritodrine hydrochloride, neutropenia, tocolysis

β-Adrenergic receptor agonists have been widely used for tocolysis for many years. Although ritodrine can be used with relative safety while pulse rate, respirations, blood pressure, serum glucose, potassium, and hematocrit are monitored, serious side effects have been reported. The drug has been associated with the development of pulmonary edema, myocardial ischemia, ketoacidosis, hypocalcemia, and hyperlactacidemia.[1] We did not find any reports of hematologic derangements with ritodrine in the literature.

Case report

A 22-year-old Hispanic woman, gravida 3, para 1, abortus 1, was admitted elsewhere for premature labor at 33 weeks' gestation. She was begun on a regimen of a continuous intravenous infusion of ritodrine, and contractions ceased. Other than some nausea and palpitations, she tolerated the medication without difficulty. Numerous attempts were made to wean the patient off intravenous ritodrine and maintain her on a regimen of oral medication, but contractions resumed each time. The intravenous infusion varied from 0.15 to 0.3 mg/min.

On admission the white blood cell count was 8900/mm³, with 77% segmented neutrophils, 22% lymphocytes, and 1% monocytes. Hemoglobin was 13.3 gm/dl. Three weeks later the white blood cell count had fallen to 3700/mm³, with 72% neutrophils and 37% lymphocytes. The white blood cell count eventually dropped to 2100/mm³, with 2% segmented neutrophils, 2% band forms, 63% lymphocytes, 2% monocytes, and 1% basophils. Hemoglobin remained 11 to 12 gm/dl, and platelet count also stayed in the normal range. When a nadir of absolute neutropenia with neutrophils of 84/mm³ was reached, she had been receiving intravenous ritodrine for 26 days and had received no other medication. Ritodrine was discontinued and she was transferred to our university hospital. Because she was in labor, a repeat cesarean section was performed without complications at 37 weeks of gestation. On physical examination no splenomegaly was noted, and no sites of infection were identified.

The patient had an uneventful postoperative course and no postpartum infectious complications occurred. Three days after operation, the white blood cell count had risen to 3700/mm³, with 39% neutrophils, 24% bands, 30% lymphocytes, 15% monocytes, and 1% basophils. At a checkup 6 weeks postpartum all hematologic indices remained in the normal range. The baby was normal, left the hospital with the mother on the fifth postpartum day, and has had no developmental difficulties.

Comment

This is the first report of neutropenia developing in a patient after almost 1 month of intravenous ritodrine for tocolysis, given in the recommended doses. The patient had no history of leukopenia or recent exposure to another drug or toxin. The leukopenia and neutropenia resolved very rapidly, within 3 or 4 days, after cessation of ritodrine. Bone marrow examination was not performed because of this rapid resolution. Rechallenge with ritodrine also was not carried out because of the risk of neutropenia and the possible necessity for prolonged intravenous administration. Follow-up 3 years later has not revealed any recurrent neutropenia or blood disorder.

Drug-induced agranulocytosis may be the result of decreased precursor cell proliferation, cell loss in the maturation process, increased margination in the circulation, increased peripheral destruction, or a combination of these mechanisms.[2] The pathophysiologic mechanisms of drug actions leading to neutropenia are poorly understood. Both toxic effects of drugs on neutrophil formation and immunologic mechanisms causing accelerated cell destruction have been proposed and demonstrated in a few instances.

In this instance the neutropenia was probably a non–

dose-related idiosyncratic reaction. The slowly declining neutrophil count and rapid recovery after drug withdrawal in this case suggest suppressed neutrophil production or production of antibodies leading to immunologic injury of neutrophils. The exact mechanisms by which ritodrine may induce neutropenia are not known but this complication needs to be considered in cases where long-term administration of ritodrine is contemplated.

Meningoencephalitis caused by *Histoplasma capsulatum* complicating pregnancy

James A. McGregor, M.D., C.M., B. K. Kleinschmidt-DeMasters, M.D., and John Ogle, M.D.

Denver, Colorado

We report what appears to be the first established case of disseminated histoplasmosis in pregnancy. Involvement of the central nervous system made treatment difficult, and the course of disease required iatrogenic preterm delivery of an uninfected fetus. Aspects of pathogenesis, diagnosis, interaction with pregnancy, and treatment for this common infection, hitherto unreported in pregnancy, are presented. (Am J Obstet Gynecol 1986;154:925-31.)

Key words: Pregnancy, meningoencephalitis, meningitis, *Histoplasma capsulatum*, histoplasmosis

Histoplasmosis is a frequently asymptomatic mycosis caused by the yeast phase of the dimorphic fungus *Histoplasma capsulatum*.[1] The disease is endemic within the Mississippi, Missouri, and Ohio river basins in the United States. Histoplasmosis occurs outside North America and was initially described by Darling in 1906 among natives of the Panama Canal Zone. Although immunologic studies suggest that up to 50% of adults living within endemic areas have had histoplasmosis, there are only isolated reports of healed, asymptomatic, or chronic pulmonary histoplasmosis that were identified antenatally or at time of autopsy for choriocarcinoma.[2-4] There do not appear to be other reports of disseminated histoplasmosis occurring during pregnancy.[1, 5] We report the first such observation in a 26-year-old, primigravid Panamanian woman, whose pregnancy was complicated by fatal *H. capsulatum* meningoencephalitis necessitating delivery of an 810 gm preterm infant by cesarean section.

Case report

A 26-year-old Panamanian woman, gravida 1, para 0, was admitted at 26 weeks of gestation to the psychiatric ward of her local hospital with a diagnosis of "psychosis due to pregnancy" because of a 3-month history of headaches and 3 weeks of increasing confusion. She had immigrated to the United States from her native Panama as a United States Army dependent 6 months before her illness and had not traveled after her arrival in Colorado. Her father had expired of miliary tuberculosis 2 years before her arrival in this country. The patient's previous tuberculin skin test status was unknown. Previously she had been healthy and appeared well nourished. There was no known exposure to blood products, parenteral substance abuse, or exposure to individuals at risk for acquired immune deficiency syndrome. During this 5-day hospitalization, the patient developed right seventh nerve palsy and increasing lethargy ending in coma. A tuberculin skin test was positive (2 cm induration), but histoplasmin and coccidiodin tests were negative. Cerebral spinal fluid examination showed a red blood cell count of 3850/mm^3, white blood cell count of 110/mm^3 (segmented neutrophils 30%, lymphocytes 59%, and monocytes 11%) with protein, 546 mg/dl, and glucose, 10 mg/dl. Peripheral white blood cell count was 15,000/

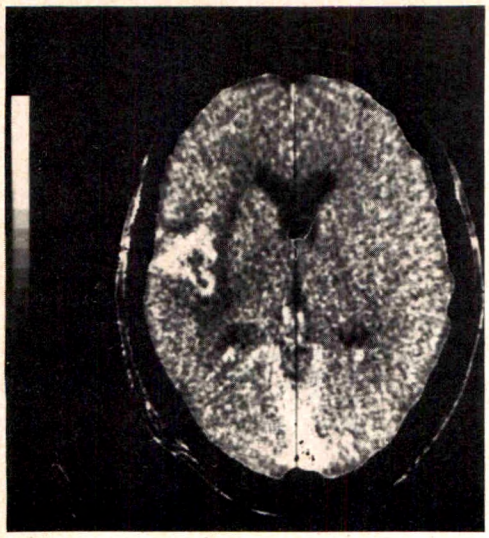

Fig. 1. Computed tomographic scan demonstrating recent infarction of right perisylvian area. See Fig. 2 for correlation.

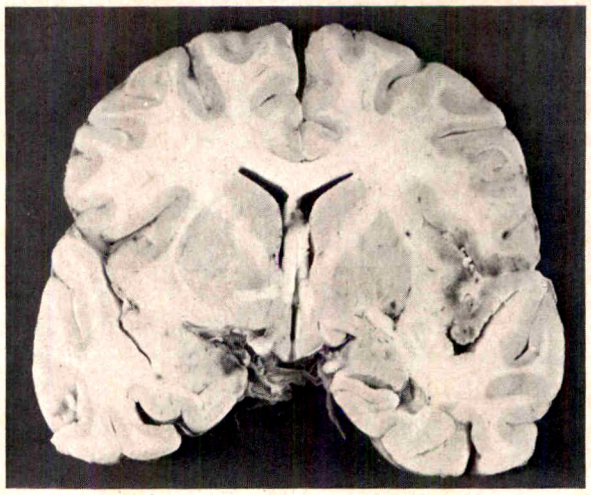

Fig. 2. Coronal brain section at the level of the anterior commissure illustrating the discolored infarctions of the right perisylvian cortex and the left amygdala. mm³, with segmented neutrophils 86%, bands 1%, lymphocytes 9%, and monocytes 4% with an erythrocyte sedimentation rate of 89 mm/min. Chest roentgenogram and other laboratory tests were within normal limits. The patient was transferred to the University of Colorado Health Sciences Center and treated for presumed tuberculous meningitis in pregnancy. She was treated with parenteral isoniazid, ethambutol, rifampin, and supplementary pyridoxine and multisystem support. Computed tomograms demonstrated acute grade II/V hydrocephalus with probable infarction of the sylvian region compatible with obstruction of the right middle cerebral artery (Fig. 1). These findings were confirmed by a cerebral angiogram. A decompressing ventriculoperitoneal shunt was placed, with no clinical improvement. Subsequent computed tomograms demonstrated changes compatible with further infarction of anterior lobe tissues supplied bilaterally by the anterior cerebral arteries. Focal right-sided and grand mal seizures developed and were treated with phenobarbital and Dilantin. Serial cerebrospinal fluid examinations of stained smears, india ink preparations, and bacterial, mycobacterial, fungal, and viral cultures had been negative.

On the twelfth day of hospitalization cerebrospinal fluid IgM-histoplasma antibody obtained at the referring hospital was reported as positive. Antituberculous medications were discontinued, and administration of intravenous amphotericin B was begun. The following day, previously obtained cerebrospinal fluid fungal cultures yielded multiple colonies of mold compatible with *H. capsulatum*, confirming the diagnosis of histoplasma meningitis. The mother subsequently suffered a stormy course marked by aspiration pneumonitis requiring intubation and intensive respiratory support. A bronchopulmonary fistula with pneumothorax and pneumomediastinum developed, requiring placement of two chest tubes.

The pregnancy had appeared to be uncomplicated before the onset of symptoms. On admission, examination of clinical dating parameters, uterine size, and fetal ultrasound measurements were compatible with 26 weeks' gestation. The fetus was vertex, and the cervix was long and closed. The fetus was monitored with periodic ascultation and three-times-weekly nonstress testing with an external monitor. Coincident with maternal deterioration, uterine contractions were noted and treated with magnesium sulfate, 2 gm/hr intravenously. Two doses of 12.5 mg of betamethazone were given intramuscularly. Ninety-six hours later, on the fourteenth hospital day, concurrent with further maternal respiratory deterioration and worsening hypoxemia, uterine contractions resumed, and fetal monitoring showed sustained fetal tachycardia of 160 to 170 bpm and repetitive late decelerations. A biophysical profile with ultrasound determined the presence of amniotic fluid, decreased tone, and no fetal movement or breathing. Measures were taken to improve maternal oxygenation, but no change was observed in fetal findings; a primary cesarean section was performed. A 810 gm male infant of 27 to 28 weeks' gestation was delivered (Apgar scores of 3 at 1 minute and 3 at 5 minutes) and immediately intubated in the delivery room. The infant developed hyaline membrane disease and required ligation of a patent ductus arteriosus. At 9 months of age, the infant has chronic lung disease necessitating respiratory support. Shortly after birth and before routine administration of vitamin K, the infant developed bleeding from catheter sites. Laboratory workup and treatment results were consistent with vitamin K deficiency; vitamin K was given. The placenta was grossly and histologically normal. Bacteriologic and fungal cultures of the placenta were negative. Cord blood and urine obtained at 2 weeks of age

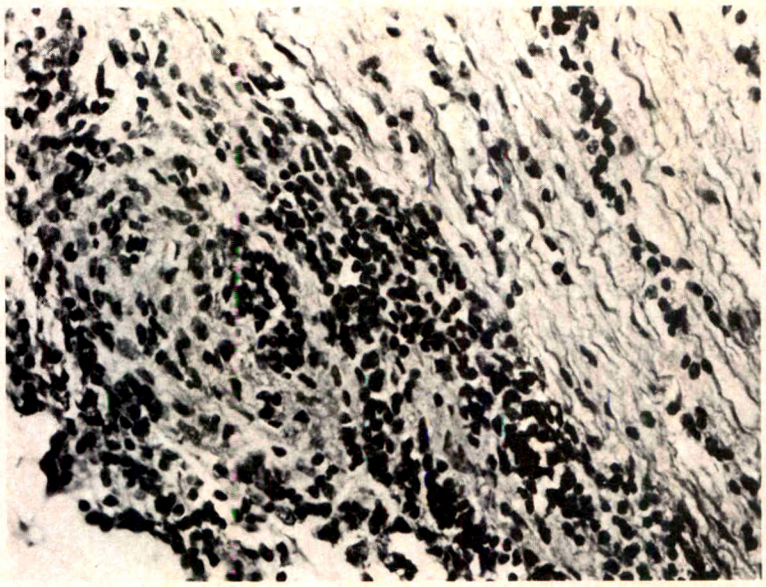

Fig. 3. Histiocytic and lymphocytic inflammation with ill-defined granuloma formation in leptomeninges and parenchyma of the left third cranial nerve. (Hematoxylin and eosin; ×325.)

were negative for IgM-antihistoplasma antibody and antigen.

After delivery the mother transiently improved but died without gaining consciousness on the twenty-fourth hospital day from respiratory insufficiency secondary to massive bronchopulmonary air leaks and aspiration pneumonitis.

Autopsy findings

Necropsy was limited by permit to biopsy sampling of organs. The unfixed brain weighed 1260 gm and demonstrated mild opacification of the meninges with gyral flattening most prominent over the base. Freshly cut coronal sections revealed a recent softened, noncavitated cortical infarction in the right perisylvian region (Fig. 2). A smaller similar cortical infarct was noted in the left amygdala (Fig. 2). The lateral, third, and fourth ventricles were mildly compressed by edema. Microscopically the meninges showed widespread plasmacytic, histiocytic, and lymphocytic inflammation with secondary involvement of cranial nerves, as well as the media and adventitia of adjacent vessels (Fig. 3). Vessels overlying the right perisylvian infarct were encompassed by caseous necrosis (Fig. 4), and some showed mild reactive intimal proliferation (Fig. 5). The infarct showed abundant macrophage infiltration and proliferated capillaries and appeared to be several weeks in age. Microscopic infarctions were also noted in the hippocampus, parahippocampal gyrus, cerebellum, midbrain tectum, and pontine tegmentum. Staining with Grocott methenamine silver demonstrated numerous small budding yeast in the leptomeninges, vessels, cranial nerves, and infarcted brain tissue (Fig. 6). Bacterial, viral, fungal, and mycobacterial cultures were negative except for *H. capsulatum*. Examination of the lungs demonstrated diffuse congestion and consolidation and a bronchopulmonary fistula in the right upper lobe. A single enlarged caseous node in the left lung hilum was found to be centrally necrotic with peripheral fibrosis but without giant cells or calcification. Methenamine silver–stained sections of this node demonstrated abundant small budding yeast forms of histoplasmosis (Fig. 6). Examination of lung parenchyma revealed numerous foamy macrophages in alveolar spaces along with hyperplastic alveolar lining cells and interstitial fibrosis, but no yeast forms were noted. Except for the healing postpartum uterus and a congested liver, all other organs were grossly and microscopically unremarkable; examination included negative special stains for fungi and mycobacteria.

Comment

The hypheal form of *H. capsulatum* exists in soil—as well as in bird, bat, and other small mammalian excreta—in endemic areas. Histoplasmosis is acquired by the inhalation of macroconidia or microconidia or mycelial fragments of *H. capsulatum* in dust. The lower respiratory tract and the reticuloendothelial system are the primary sites of infection. *H. capsulatum* may disseminate within lymph or blood, or perhaps yeast-laden macrophages, to involve liver, spleen, central nervous system, and other body sites.

Despite the frequency of occurrence of histoplasmosis within endemic areas and the presumed infection among pregnant women living in these areas, little is known regarding interactions between this potentially severe fungal infection and pregnancy. Wheat's un-

published observations of 175 Indiana women with histoplasmosis included seven pregnant individuals who may be added to previously reported women with histoplasmosis and intercurrent pregnancy.[5] These initial observations and the paucity of previous medical reporting of histoplasmosis in pregnancy suggest that dissemination during the immunobiologic alterations of pregnancy is not a feature of histoplasmosis.

In contrast, dissemination of coccidioidomycosis in women occurs almost entirely during pregnancy, and the later coccidioidomycosis is acquired during pregnancy, the greater the frequency of dissemination.[6, 7] Dissemination of coccidioidomycosis during pregnancy is also more likely to be fatal.[7] *Coccidioides immitis* is the only fungi reported to cross the placenta and cause hematogenous infection of the fetus.[7] At least 10 reports of cryptococcosis and four cases of North American blastomycosis in pregnant women have been reported.[8, 9] One of four infants born to women with active blastomycosis acquired this infection.[10] Although it was suggested that the infant acquired the fungal infection through transplacental transmission, the

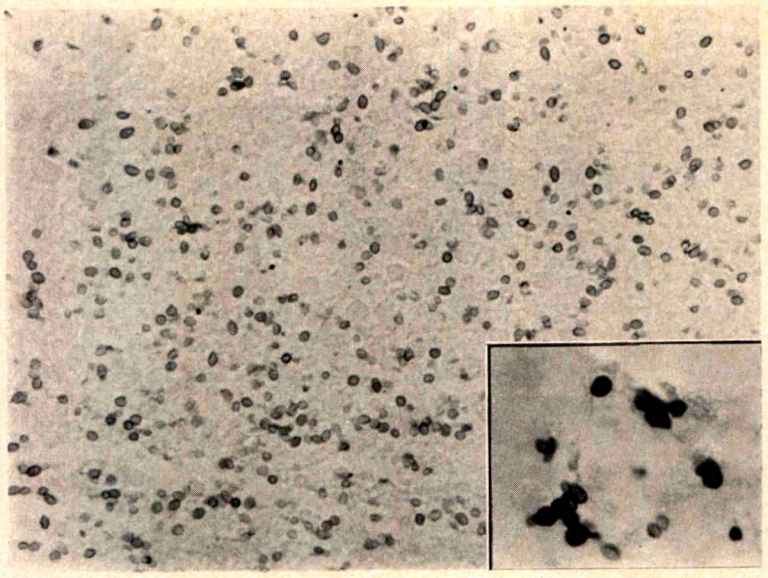

Fig. 6. Numerous *H. capsulatum* found in the caseous hilar lymph node. Inset: The budding yeast seen at higher power was also easily demonstrable in the leptomeninges. (Grocott methenamine silver; ×325. Inset: ×850.)

mother had *Blastomyces dermatitides* in the urine, and the perinate may have aspirated infectious material at birth. Both histoplasmosis and blastomycosis genital infections from sexual contact have been reported.[11, 12] Lack of placental and/or fetal infection in this case of disseminated histoplasmosis confirms the observation that visceral fungal infections, including histoplasmosis in the absence of birth canal infection, do not put the fetus at high risk for intrauterine infection. Unexplained anatomic or immunologic attributes of trophoblastic tissue may account for the observed rarity of placental fungal infection.

Cell-mediated immunity. An integrated immune response relying primarily on cell-mediated immunity protects the body from invasion by fungi.[13] Limited observation of nonpregnant patients with healed histoplasmosis does not demonstrate increased risk of exacerbation or dissemination during immunosuppression. On the other hand, treatment with corticosteroids or other immunosuppressive agents increases the risk of dissemination and death in active histoplasmosis and coccidioidomycosis and also increases the risk of acquiring blastomycosis. Pregnancy induces a state of relative immunosuppression that includes decreased (1) numbers of helper T cells, (2) natural killer cell activity, (3) lymphocyte blastogenic responses, (4) chemotaxis, (5) rejection of skin allografts, and (6) delayed-type skin test reactivity.[5] These immune alterations are most prominent in the third trimester of pregnancy and may account for the observed worsened course of blastomycosis late in pregnancy.[5, 6]

Invasive fungal infections, including histoplasmosis, have been documented to independently mediate systemic immunosuppression.[14-15] Fungal infection–induced immunosuppression is nonspecific and requires the ongoing presence of organisms. Apparently the immunosuppression is mediated by suppressor cells.[13-15]

Our patient had not been in an endemic area for 6 months and presumably had acquired histoplasmosis in her native Panama, since histoplasmosis is very rare among natives of nonendemic areas such as Colorado. Despite the negative admission chest roentgenogram, the histologic finding of fungal forms consistent with *H. capsulatum* in this patient's lung granuloma suggests that the histoplasmosis infection, although contained, was ongoing and originally had a primary pulmonary focus. The histoplasmosis infection may have mediated a degree of immunosuppression that was additive with the effect of pregnancy, as well as serving as a source of dissemination to the central nervous system. Although it is difficult to be sure, both the rarity of histoplasmosis in Colorado and the patient's prolonged history of headaches suggest that the woman acquired the infection in Panama and that symptoms only became apparent when the infection spread to the central nervous system during the physiologic immunosuppression of pregnancy.

Diagnosis. Diagnosis of the various expressions of *H. capsulatum* infection is frequently difficult. Awareness of the varied expression of histoplasmosis remains the prerequisite for the diagnosis of this and other fungal infections.[1] A history of exposure to environmental sources is infrequent, and physical and roentgenographic findings are not specific.[1] Histoplasmin antigen skin testing or complement-fixation serologic tests have not proved useful, especially in disseminated histo-

plasmosis.[16] Microbiologic and/or pathologic identification are essential for reliable diagnosis.[1] With repeated cultures of sputum and cerebrospinal fluid, nearly all instances of active lung or meningeal infection will yield *H. capsulatum*.[1, 17] Any biopsy specimens taken from a patient in whom histoplasmosis is a possibility should be cultured for fungi and microscopically examined after staining with methenamine silver. Examination of cerebrospinal fluid commonly demonstrates findings similar to tuberculosis meningitis with increased levels of protein, hypoglycorrhachia, and a predominance of lymphocytes and monocytes.[17] Recently developed assays for *H. capsulatum* antigen-specific IgM or IgG antibody in body fluids (blood, urine, cerebrospinal fluid, etc.) are highly promising but remain to be fully evaluated. In this patient, cerebrospinal fluid findings and a positive tuberculin skin test suggested tuberculosis, but cerebrospinal fluid fungal culture and cerebrospinal fluid anti–histoplasmosis IgM confirmed the diagnosis.

Treatment. Treatment of any central nervous system fungal infection is difficult, since no antifungal agent crosses blood/brain barriers adequately. Optimal therapy for disseminated histoplasmosis requires completion of a full course of intravenous amphotericin B (1.5 to 2.5 gm).[17] The role of alternative or concomitant treatment with other antifungal agents, including ketoconazole, 5-fluorouracil, and miconizole, remains unsettled. None of these agents are likely to surpass the treatment efficacy of amphotericin B.[1] The analysis of Ismail and Lerner of over 20 mother-fetus pairs demonstrates that amphotericin B crosses the placenta and reaches roughly one third of maternal levels within the fetus without evidence of toxicity or teratogenesis.[18] These authors noted that adverse effects of amphotericin B, including nephrotoxicity with azotemia and/or hypokalemia, appear no worse in pregnant than in nonpregnant patients.[18] Ketoconazole has the practical advantages of oral administration but may be inadvisable during pregnancy on the basis of observed teratogenecity in laboratory animals and transient inhibition of host–steroid hormone synthesis.[19] Rifampin, used here as therapy for presumed *Mycobacterium tuberculosis* infection, enters the central nervous system but is of unproven benefit for fungal central nervous system infection. Rifampin appears safe in pregnancy after organogenesis is completed. As noted in this case, maternal rifampin (and phenytoin) administration may be associated with neonatal coagulopathy, which is reversible with maternal or neonatal vitamin K administration.[20, 21] Experience with any therapy of invasive fungal infection among pregnant women and their progeny remains limited. Surveillance for fetal well-being with contemporary methods of fetal evaluation should be performed during treatment. Authorities agree that treatment of histoplasmosis with amphotericin B is indicated only in patients who have the potential for prolonged illness or death.[1]

In summary, we have described the occurrence of disseminated histoplasmosis with spread to the central nervous system in a pregnant woman who had immigrated from an endemic area 6 months before the recognition of illness. Pregnant women are increasingly frequent travellers and are thus exposed to varied endemic illnesses worldwide. Careful history-taking for travel or residence in different geographic regions is frequently crucial for the timely diagnosis and treatment of many infectious diseases, including histoplasmosis. Incompletely understood immunologic alterations induced by pregnancy and ongoing histoplasmosis probably played roles in this woman's progressive illness. Cesarean section of a premature infant was mandated because of fetal distress caused by ultimately fatal maternal respiratory failure. Delay in accurate diagnosis of histoplasma-mediated meningoencephalitis impaired treatment. Pregnancy-associated immune alterations are documented to potentiate fungal infections such as coccidioidomycosis and blastomycosis. This case suggests that active histoplasmosis may also be aggravated, on occasion, during pregnancy.

We wish to acknowledge the clinical and laboratory consultations of Dr. Lawrence Wheat, Wischard Memorial Hospital, Indianapolis, Indiana.

Sequential nonstress testing with use of each fetus as its own control

Lawrence D. Devoe, M.D., Ramon Castillo, M.D., Joan McKenzie, R.N., B.S.N., Nancy Searle, B.A., Beth Robinson, B.A., and Harry Davis, M.S.

Augusta, Georgia

The sequential nonstress tests of 126 high-risk fetuses were assessed for baseline fetal heart rate, acceleration frequency, amplitude, and duration and the observance of fetal heart rate decelerations. In 108 fetuses (563 tests) with normal perinatal outcomes, no significant trends in these parameters were found. In 18 fetuses (104 tests) with perinatal compromise, 16 had significantly declining acceleration frequencies, 15 had decreasing acceleration duration, four had rising mean baseline rates, and seven, in their last test before delivery, had repetitive late or severe variable decelerations. The last tests of 11 of these 18 fetuses met institutional criteria for reactivity. When the nonstress tests of compromised fetuses were viewed sequentially, acceleration frequency declined by an average of 59% and acceleration duration by an average of 40%. Sequential assessment of the nonstress test, when compared with the use of standard reactivity criteria, improved test sensitivity from 39% to 89% and negative predictive value from 91% to 98%. We conclude that sequential nonstress test assessment in individual fetuses may improve the diagnostic value of this modality and lead to earlier recognition of fetal compromise. (AM J OBSTET GYNECOL 1986;154:931-6.)

Key words: Nonstress test, high-risk fetuses, sequential testing, fetal compromise

Fetal heart rate (FHR) patterns in the third trimester are characterized by stable long-term baseline rates, cyclic oscillations in baseline rate, and movement-associated FHR accelerations. Sequential FHR changes, for example, decreased frequency of movement-associated FHR accelerations, loss of baseline variability, and the appearance of late FHR decelerations, may precede overt fetal compromise. However, there are limited human data on the magnitude of these changes needed to achieve diagnostic significance or the order in which they evolve in antepartum FHR tracings. Experimental evidence, obtained from chronic animal preparations,[1-4] suggests that hypoxic stress may have a variable impact on the FHR baseline, ranging from mild tachycardia, the loss of reactive accelerations, and altered FHR variability to the evolution of late decelerations and bradycardia. These data, from different species and under varied experimental conditions, are difficult to compare and apply directly to clinical antepartum testing.

The nonstress test is a means of providing rapid assessment of fetal condition.[5-7] Clinical interpretation is based on the presence or absence of movement-associated FHR accelerations, and individual tests are used in diagnosis. Typically this approach does not consider the relationship of previous nonstress tests to subsequent tests and has been criticized for its failure to detect the early appearance of fetal compromise.[8] Sequential comparison of nonstress tests, with use of each

fetus as its own control, is an alternative approach that has not been adequately explored.

We undertook this study to examine selected components of the nonstress test to determine whether there were significant sequential trends in any of the nonstress test parameters (mean baseline rate, the frequency, amplitude, or duration of movement-associated FHR accelerations, or the presence of decelerations) which could be used to improve the ability of the nonstress test to provide evidence of fetal jeopardy.

Material and methods

One hundred twenty-six fetuses were examined in the antenatal assessment unit of the Medical College of Georgia Hospital and Clinics. All fetuses were at least 33 weeks' gestational age, had no ultrasound evidence of major anomalies, and were tested for the reasons listed in Table I.

Testing was performed in a standardized manner with use of a previously reported institutional protocol.[7] All tests were conducted for a minimum of 30 minutes, with use of Hewlett-Packard 8040A electronic monitors in the Doppler mode. Fetal movements were entered by means of a remote event indicator and were corroborated by experienced observers. The nonstress tests were analyzed retrospectively with the investigators blinded to perinatal outcome. The following parameters were assessed: (1) mean 1-minute baseline heart rate, exclusive of accelerations, decelerations, or signal loss; (2) frequency of movement-associated FHR accelerations exceeding 15 bpm amplitude and 15 seconds' duration; (3) mean movement-associated FHR acceleration amplitude and duration; (4) the presence of late or variable decelerations.

The following perinatal outcome parameters were considered: (1) mortality, (2) intrapartum fetal distress, (3) 5-minute Apgar score <7, (4) neonatal acidemia (umbilical arterial pH <7.20), and (5) intrauterine growth retardation.

Statistical analysis included χ^2 tests, *t* tests, runs tests, and signed rank test where appropriate; a p value of <0.05 was considered significant.

Results

Six hundred sixty-seven nonstress tests were performed on the 126 fetuses, at intervals of ≤7 days. All studies contained <10% loss of signal Each fetus underwent at least five serial nonstress tests (mean: 5.3) and was delivered within 1 week of the last test.

One hundred eight fetuses, producing 563 nonstress tests, had normal perinatal outcomes, that is, no perinatal deaths or intrapartum or neonatal complications. Eighteen fetuses had one or more of the perinatal complications listed above and underwent 104 nonstress tests. The obstetric characteristics of these two groups are compared in Table II. There were significant differences in gestational age at delivery and mean birth weight between the groups.

The runs test was applied to the individual FHR parameters of the sequential tracings from both groups. In the normal group, no statistically significant trends were noted in any nonstress test parameter (mean baseline FHR, movement-associated FHR acceleration frequency per 30 minutes, movement-associated FHR acceleration amplitude and duration). No late decelerations occurrred with spontaneous uterine contractions; 8 fetuses exhibited mild, transient variable decelerations.

Table III summarizes the pregnancies with abnormal outcomes. Sixteen of 18 fetuses had significantly declining frequencies of movement-associated FHR accelerations (Fig. 1, runs tests, $p < 0.01$). The mean decline in movement-associated FHR acceleration frequency was 59%. Although no significant trends in movement-associated FHR acceleration amplitude were noted, 15 fetuses in the abnormal group had significant declines in the mean duration of movement-associated FHR accelerations (Fig. 2, runs tests, $p < 0.01$). The mean decline in movement-associated FHR acceleration duration was 39.9%. Four of the abnormal fetuses had significantly rising FHR baselines during the sequence of their nonstress tests (Fig. 3, runs tests, $p < 0.01$). Seven of these 18 fetuses (39%) also had late or deep variable decelerations on their last tracing before delivery. Sixty-one percent (11 of 18) of these last tracings would have been classified as "reactive" by our institutional criteria, that is, three accelerations (>15 bpm, >15 seconds) in 30 minutes.[7]

Nonstress test sensitivity with use of conventional criteria was 39% but increased to 89% when the nonstress test parameters were assessed sequentially. Nonstress test specificity was 100% by both approaches. These differences were significant (signed rank testing, $p < 0.01$). Nonstress test positive predictive values were 100% by either approach, and negative predictive values were 91% (conventional criteria) and 98.2% (sequential parameters). These latter figures closely ap-

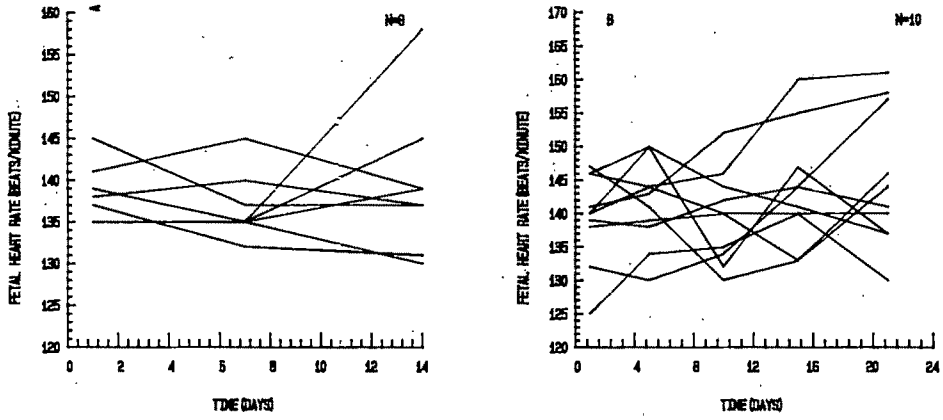

Fig. 1. *Panels A* and *B* show the trends in the acceleration frequencies in sequential nonstress tests of fetuses with abnormal outcomes, which were studied over 2-week and 3-week intervals, respectively. Sixteen of the 18 fetuses had significant declines in acceleration frequency (runs tests, $p < 0.01$).

proached but did not reach significant differences (signed rank tests, $p = 0.06$).

Comment

Fetal compromise may result from a variety of intrauterine insults. Antepartum FHR testing has been proposed as a means of detecting the presence of fetal hypoxia and possible asphyxia. Natale et al.,[2] with use of a chronic sheep model, have shown that acute hypoxia results in a markedly reduced incidence of fetal body movements. As FHR accelerations are largely triggered by fetal movements in normal third-trimester pregnancies,[10] a significant fall in the number of movement-associated FHR accelerations during subsequent nonstress tests could be a useful premonitory sign. Declines in movement-associated FHR acceleration frequency were the most consistent finding in our series and actually preceded all instances where late or severe variable decelerations subsequently occurred. In most abnormal fetuses (14 of 16) significant decreases in movement-associated FHR acceleration frequencies were accompanied by declines in movement-associated FHR acceleration duration but not amplitude. Although Ingardia et al.[9] reported that fetuses with subsequently positive contraction stress tests had quantitative differences in movement-associated FHR acceleration amplitude and duration when compared with those producing negative contraction stress tests, they did not find significant differences in the number of accelerations or fetal movements between these two groups. However, their observations were not based on sequential trends in the nonstress test. In our series, 61% of cases with abnormal outcomes met the minimum criteria for reactivity, despite a mean decline in movement-associated FHR acceleration frequency of 59%. In all instances where movement-associated FHR accelerations were present on the final tracing, their mean duration exceeded 15 bpm, although there was a mean decline in movement-associated FHR acceleration duration of 40%.

Mild acute fetal hypoxemia may also produce fetal tachycardia, as shown by Towell et al.[1] Although a mean FHR baseline exceeding 155 bpm evolved in the sequential tracings of four compromised fetuses, it was always accompanied by significant declines in movement-associated FHR acceleration frequency and duration. The significance of sequential elevation of the FHR baseline would require confirmation by larger numbers of fetuses studied with umbilical arterial blood gases.

The principle of the use of individual fetuses as their own controls has been applied to the daily fetal movement counts[11] and maternal serum estriol measurements.[12] Our data suggest that normal third-trimester

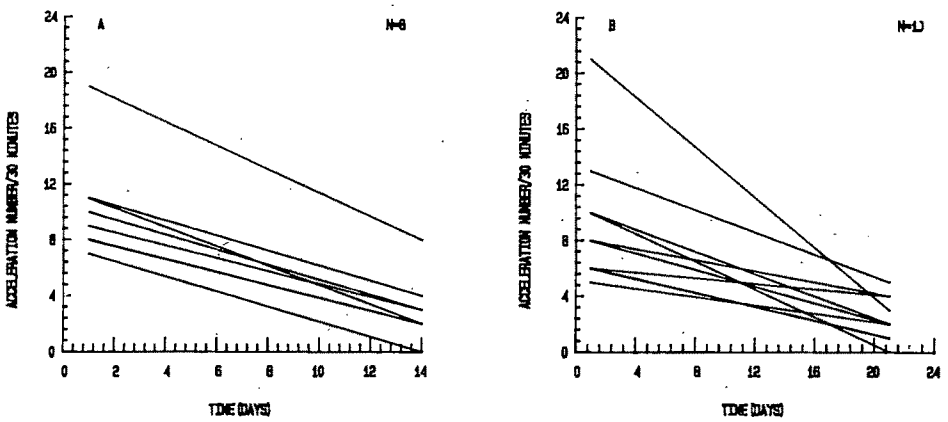

Fig. 2. *Panels A* and *B* show the trends in mean acceleration duration in sequential nonstress tests of fetuses with abnormal outcomes, which were studied over 2-week and 3-week intervals, respectively. Fifteen of the 18 fetuses had significant declines in acceleration duration (runs tests, $p < 0.01$).

fetuses, studied over intervals of 2 to 3 weeks, do not exhibit significant changes in the frequency, duration, or amplitude of movement-associated FHR accelerations. Under similarly controlled testing conditions, compromised fetuses often exhibit progressive declines in movement-associated FHR acceleration frequency and duration comparable to the pattern of change in fetal movement counts reported by Sadovsky et al.[11]

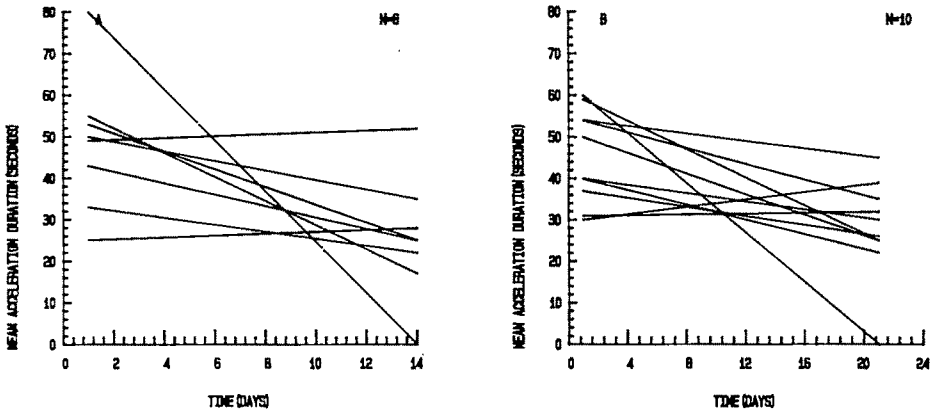

Fig. 3. *Panels A* and *B* show the trends in mean baseline fetal heart rates in sequential nonstress tests of fetuses with abnormal outcomes, which were studied over 2-week and 3-week intervals, respectively. Four of the 18 fetuses had significant elevation of their baseline heart rate exceeding 155 bpm (runs tests, $p < 0.01$).

Furthermore, these changes in nonstress test patterns preceded other signs of fetal compromise, for example, late or severe variable decelerations, which were not evident until the last tracing before delivery. As subsequent contraction stress tests were not performed on all patients, it is not possible to determine whether these decelerations would have appeared sooner. Therefore the issues of which FHR alterations provide the earliest sign of fetal compromise or whether contraction stress tests are a more sensitive primary test[13] cannot be conclusively resolved by this study. These data however, do indicate that sequential declines in movement-associated FHR acceleration frequency which exceed 50% or falls in movement-associated FHR acceleration duration which exceed 40% should prompt the performance of a contraction stress test even if the nonstress tests themselves meet normal reactivity criteria.

Criteria for nonstress test interpretation which rely solely on minimum counts of accelerations result in relatively low test sensitivity.[14] The present study supports that observation and the hypothesis that observation of additional nonstress test parameters and their serial trends might improve test sensitivity. Detection of serial changes in these nonstress test parameters may require more frequent testing, that is, every 2 to 4 days, and more careful attention to the details of FHR patterns than has been traditionally advocated. Sequential comparisons of nonstress tests may lead to earlier recognition of potentially compromised fetuses and to more timely initiation of other diagnostic tests such as the contraction stress test. These considerations are most important to clinicians who currently rely on nonstress testing as their first line of antepartum fetal assessment.

Cesarean delivery of the second twin after vaginal delivery of the first twin

Pawan K. Rattan, M.D., Robert A. Knuppel, M.D., M.P.H., William F. O'Brien, M.D., and Jose C. Scerbo, M.D.

Tampa, Florida

Cesarean birth of twin B after the vaginal delivery of twin A is an infrequent event. There is little information in the literature documenting outcome of vaginal-abdominal delivery. We reviewed our 10-year experience in the management of such cases and compared outcomes with twins delivered by repeat cesarean section and vaginal delivery in the same time period. Twenty-one cases of combined vaginal–cesarean section deliveries were managed at our institute in a 10-year period. There was no apparent increase in maternal and perinatal morbidity and mortality when twin B was delivered by cesarean section after vaginal delivery of twin A. (AM J OBSTET GYNECOL 1986;154:936-40.)

Key words: Twins, cesarean section, vaginal delivery

The increase in perinatal morbidity and mortality in twin gestation is well recognized.[1, 2] Most authors[3-5] have stressed the increased risk to the second twin. One subset of second twins, those delivered by cesarean section after vaginal delivery of twin A, have gained little attention. Earlier reports of cesarean section done for the second twin were mainly in the form of case reports.[6] Recently, Evrard and Gold[7] in reporting four cases during a 4-year period were able to add only five cases from the recent literature. Although the maternal and perinatal mortality and morbidity with this mode of delivery have been assumed to be high,[8] unless cesarean section is used for all twins, this infrequent complication cannot always be avoided.

In an attempt to define the risks of cesarean section delivery of twin B after vaginal delivery of twin A, we selected such cases from a retrospective review of our last 10 years' experience with multiple gestation.

Material and methods

All twin deliveries performed at Tampa General Hospital from January 1, 1973, to December 31, 1982, were reviewed. Twin deliveries wherein the firstborn twin was delivered vaginally and a cesarean section was done for twin B (combination delivery) were selected for this report.

Factors selected for analysis were the incidence of combination delivery during the study period, the indication for combination delivery, interval between de-

Results

During the study period there were 352 twin deliveries and 21 (6%) of these were combination deliveries that totaled 15% of the 135 cesarean births for twin gestation. Although the overall rate of cesarean births for twin deliveries rose from 16% in 1973 and 1974 to 62% in 1981 and 1982, the percentage of combination deliveries among cesarean births in twin gestation varied between 8% and 29% with no apparent trend (Table I). Indications for cesarean birth of twin B are shown in Table II. Persistent transverse lie was the most common indication followed by fetal distress. Prolonged delivery interval (approximately 1 hour or more) associated with a contracted cervix was the indication for cesarean section in 20% of the cases.

Approximately half of the cases of combination delivery occurred at or beyond 35 weeks of gestational age (52%). Four gestations (19%) were between 33 and 36 weeks and six (29%) were between 29 and 33 weeks. The mean difference in weight between twins was 193 gm with a range of 0 to 1195 gm. A weight difference of >250 gm was seen in only four cases. In three, twin A weighed more than twin B, and in one, twin B weighed more than twin A. Seven infants weighed <1500 gm (17%), 28 (66%) weighed between 1500 and 2500 gm, and seven (17%) weighed >2500 gm.

The mean interval between deliveries was 38 minutes with a range of 12 to 115 minutes. The interdelivery interval did not appear to influence neonatal condition as reflected by the distribution of low Apgar scores (Table III). One-minute Apgar scores of <7 were more common in twin B, but 5-minute Apgar scores were similar between the two groups. Two of the three infants with low 5-minute Apgar scores in the cesarean birth group were delivered for intrapartum fetal distress after the delivery of twin A. There were two perinatal deaths (47 per 1000), both of which occurred in the twins delivered vaginally. The stillbirth was an intrapartum fetal death during maternal transport for preterm labor. Twin B was delivered by cesarean section because of fetal distress. The neonatal death occurred in a newborn infant at 30 weeks of gestation after prolonged rupture of the membranes. Neonatal cultures revealed group B streptococcal sepsis. Twin B, delivered by cesarean section because of breech presentation, had an uneventful neonatal course without evidence of infection.

A comparison of birth weights and Apgar scores of all twins delivered during the study period (at this institution) were grouped according to method of delivery (Table IV). The comparisons between groups revealed that the only significant difference was in the 1-minute Apgar score for twin B. Second twins delivered by repeat cesarean section had higher 1-minute Apgar scores than those delivered vaginally or by cesarean section after a vaginal delivery of twin A. The 5-minute Apgar scores for these groups, however, did not differ statistically.

Table IV. Birth weights and Apgar scores according to method of delivery

Group	n	Twin A			Twin B		
		Weight (gm)	*1 min Apgar score*	*5 min Apgar score*	*Weight (gm)*	*1 min Apgar score*	*5 min Apgar score*
Repeat cesarean section	18	2207	7.43	8.64	2164	7.85*	8.78
Primary cesarean section	115	2188	7.07	8.49	2134	6.64	8.39
Combination	21	1987	7.04	8.13	1999	5.52*	7.95
Vaginal	198	2153	6.83	8.23	2144	6.20*	7.87

*$p<0.05$, Duncan's multiple range test; difference between repeat cesarean section versus combination and repeat cesarean section versus vaginal delivery.

All mothers received intraoperative antibiotic prophylaxis. During this 10-year period, although prophylactic regimens varied between triple antibiotic therapy in earlier years to single antibiotic prophylaxis in recent years, the regimen used did not appear to influence the outcome. Postpartum febrile morbidity occurred in six mothers (28%) but significant febrile morbidity leading to prolonged hospital stay was seen in only three mothers (14%). In the patients with prolonged hospital stay, the following risk factors were present: severe anemia, severe preeclampsia, and intrauterine manipulation in a case of failed breech extraction. Overall, hospital stay varied between 5 and 13 days with a mean of 6.7 days and a median of 6 days.

Comment

In an effort to reduce perinatal mortality and morbidity, use of cesarean section as a method of choice for delivery of twins has been advised if one or both twins presents as a breech or is in a transverse lie.[9, 10] When vaginal delivery is planned, vaginal delivery of twin B is anticipated after twin A has been delivered. At times, however, this becomes difficult or unwise. Because of the paucity of information regarding this subject, physicians may be reluctant to perform a cesarean birth for twin B when twin A is delivered vaginally. Infallible diagnosis before delivery and cesarean section for all twin pregnancies would be required to avoid this infrequent possibility. We found that 21 of the 352 twins delivered (6%) required cesarean section after vaginal delivery of twin A, totaling 15% of all cesarean births (n = 135) in twin pregnancies. Even with liberal use of cesarean birth since 1979 (Table I), 11 of the 85 cesarean sections done in twins were for twin B and they formed 13% of all cesarean births in twin pregnancies.

In up to 40% of cases, both twins may present by the vertex[11] and would therefore be candidates for vaginal delivery, according to most recommendations. However, failure to diagnose twins before the onset of labor could be expected to contribute to the need for cesarean section of the second twin. In our review lack of diagnosis before labor occurred in 35% of all cases. Additionally, unexpected low birth weight may become apparent only after delivery of the first twin and cesarean section has been proposed as an optimal route of delivery for twin B.[12]

In their recent review of this subject, Evrard and Gold[7] had no cases where the indication for cesarean section was prematurity, cord prolapse, or fetal distress. Both perinatal deaths, moreover, occurred in the twin delivered by cesarean section. In our experience both perinatal deaths were in the twin delivered vaginally. This difference in experience may be due to the limited sample size of the series or may reflect differing methods of management of twin B.

Two important observations from this series should be stressed. First, even with liberalized indications, the necessity for cesarean section may not always be recognized before delivery. Second, in this small series there appeared to be little correlation between interdelivery interval and outcome; however, a larger series is required to support definitive correlations between interdelivery intervals and outcomes.

The need for adequate antepartum diagnosis for optimal management of twin gestation is obvious and has been stressed by various authors.[13, 11] In view of the continued problem of inadequate prenatal care and the cost efficacy of routine sonographic examination in all patients, however, the problem of undiagnosed twins is likely to remain with us. As noted in this series, moreover, even with optimal conditions for vaginal delivery, intrapartum events may alter the management of twin B.

The feasibility of such an alteration was demonstrated in the outcome of twin B. Although an inter–twin delivery time of 15 to 20 minutes has been suggested as a limit of safety, there appeared to be no great increase in compromised infants delivered by cesarean section at intervals up to 2 hours. Beginning in 1979, all second twins were evaluated with a fetal monitor, and after delivery of twin A a fetal electrode was placed as soon as it was found safe to do so. The overall outcome of newborn infants delivered in such a manner,

moreover, was not significantly different from that of those delivered vaginally.

In most reports of post–cesarean section morbidity, infection has been described as the most important complication, ranging from 19% to 51%.[15, 16] In our review, significant febrile morbidity leading to prolonged hospital stay was seen in three of 21 patients (14%). All had predisposing factors such as severe anemia, severe preeclampsia, or intrauterine manipulation.

This review, which forms the largest number of such cases reported, suggests that whenever indications exist, cesarean section can be performed safely for the delivery of twin B after vaginal delivery of twin A. We recognize that indications for cesarean section are controversial; however, in this series there was no excessive increase in maternal morbidity and neonatal morbidity or mortality due to cesarean birth for twin B. We therefore feel that cesarean birth of twin B after vaginal delivery of twin A is a safe and acceptable method of management in a selected group of twin deliveries, but we do not condone undue hesitation in clinical decision making.

Lactation suppression and puerperal fever

Oscar D. Almeida, Jr., M.D., and David Z. Kitay, M.D.
Mobile, Alabama

Seventy-five puerperal women who did not wish to breast-feed were treated with bromocriptine mesylate (Parlodel) or placebo in a prospective, randomized, double-blind study. Results revealed a puerperal fever incidence of 18.6%, 13.3% of which was due to breast engorgement and 5.3% to an infectious process. Parlodel prevented puerperal fever in 87.9% of patients. If Parlodel was given within 18 hours of delivery, physiologic puerperal fever was prevented in 100% of cases. (Am J Obstet Gynecol 1986;154:940-1.)

Key words: Lactation, breast engorgement, puerperal fever, milk fever, bromocriptine mesylate (Parlodel)

The purpose of this study is to prove existence of puerperal fever due to breast engorgement and that prevention of this fever can be achieved by lactation suppression.

Material and methods

A prospective, randomized, double-blind study was conducted with 92 puerperal patients at the University of South Alabama Medical Center from January to May, 1985. Healthy patients were recruited from the obstetrics service according to the following criteria: (1) Patients were in the immediate puerperium, having had an uncomplicated pregnancy; they had no medical illnesses, were afebrile in the intrapartum period, and were delivered vaginally. (2) Selection was without regard to age, race, or parity. (3) Patients did not intend to breast-feed and agreed to suppress postpartum lactation by pharmacologic means. (4) Patients had gestational ages ≥36 weeks at delivery. (5) Patients remained hospitalized for 72 hours in order to allow collection of sufficient objective data. Patients were supplied medicine bottles in routine fashion after vital signs stabilized. Forty-five patients received Parlodel, and 47 received a placebo. Tablets from unknown numbered bottles were dispensed until postpartum day 3 (day of discharge), at which time patients were given Parlodel for 2 weeks. Before discharge, a fasting 7 ml blood sample was obtained from the antecubital space, spun down, and sent for assay of serum calcium.

Puerperal fever was defined as one or more oral readings of ≥100° F (37.8° C). Vital signs were recorded every 4 hours. Patients were instructed to notify the nurse when breast engorgement began to document time. Febrile episodes were investigated by physical examination, complete blood count with differential count, cervical culture, microscopic analysis, and culture of a catheterized urine specimen. Fever was considered due to physiologic breast engorgement if four postulates were satisfied: (1) fever of a transient nature, (2) appearance of a temperature spike within 2 hours of onset of breast engorgement and lactation, (3) no other signs or symptoms (including laboratory studies) present suggesting an infectious process, (4) resolution of fever without use of antibiotics.

Table I. Summary of puerperal fevers

	Bromocryptine mesylate (Parlodel)		*Placebo*	
	n	%	*n*	%
Febrile	0	0.0	6	9.0
Afebrile	32	47.8	29	43.2

Fisher's exact test (n = 67 patients; no infectious source; received bromocriptine mesylate or placebo within 18 hours post partum): p = 0.03.

Eight patients were excluded: Four had an obvious infectious cause of puerperal fever, and four received Parlodel more than 18 hours post partum.

Results

Seventy-five patients satisfied study criteria. Seventeen patients excluded were discharged early (insufficient objective data collection) or because of errors in taking medication. Fourteen of 75 patients had puerperal fever (18.6%). Ten (13.3%) were considered lactation-associated. Three febrile patients had upper respiratory infections and one developed endometritis with cultured β-hemolytic streptococci and staphylococci. Four of 10 febrile patients with breast engorgement were treated with Parlodel, and the remaining six received placebo. It was statistically significant that if the time from delivery to administration of Parlodel

Table II. Summary of puerperal fever in the study population

	Total patients	% of total population	% of total fevers	Oral temperature (°F)	
				Range	Mean
Physiologic breast engorgement and lactation	10	13.3	71.4	100.0-101.2	100.4
Upper respiratory infection	3	4.0	21.4	100.0-101.0	100.5
Endometritis	1	1.3	7.1	102.8	
All causes	14	18.6	–	100.0-102.8	100.8

was <18 hours, no patient manifested physiologic puerperal fever (Table I). Puerperal fevers are summarized in Table II. Serum calcium levels were subnormal or low normal in 95% of patients regardless of medication, placebo, or fever.

Comment

The double-blind study demonstrates that milk fever is a true physiologic entity, and suppression of lactation with Parlodel, if given within 18 hours of delivery, eliminates this fever.

At least one study and several texts unequivocally deny puerperal fever associated with breast engorgement despite Meigs' elegant description more than 130 years ago. Roser[1] suggested empirical antibiotic therapy could be withheld to avoid an iatrogenically complicated puerperium, and suppression of lactation would eliminate the fever. Veterinary medicine has long recognized the devastating effects of milk fever in cattle, such as hypocalcemia, changes in neuromuscular tone, tremor, paresis, coma, and death.[2]

Puerperal fever in the past was undoubtedly attributed to genitourinary tract infection. At present it is still caused by cystitis, endometritis, atelectasis, and pelvic phlebitis. Results of this study show that puerperal fever among women with a benign intrapartum course may be caused by physiologic breast engorgement, and Roser's suggestion of eliminating empirical antibiotics is valid.

Bromocriptine mesylate (Parlodel) and placebos were supplied by the Pharmaceutical Division, Sandoz Inc., East Hanover, New Jersey.

Atraumatic delivery in cases of malpresentation of the very low birth weight fetus at cesarean section: The splint technique

Maurice L. Druzin, M.D.
New York, New York

A technique to assist in the atraumatic delivery of the very low birth weight fetus in cases of malpresentation at cesarean section is described; the technique minimizes potential trauma associated with version and/or extraction techniques. Use of uterine relaxing anesthetic agents and subsequent risk of hemorrhage are avoided. (Am J Obstet Gynecol 1986;154:941-2.)

Key words: Premature fetus, malpresentations, atraumatic cesarean delivery

From the Department of Obstetrics and Gynecology, The New York Hospital–Cornell Medical Center.
Received for publication October 10, 1985; accepted October 14, 1985.
Reprint requests: Maurice L. Druzin, M.D., 525 East 68th St., M-036, New York, NY 10021.

When delivery is inevitable, current management of the very low birth weight fetus (501 to 1500 gm, 26 to 32 weeks' gestation) consists of atraumatic delivery and intensive neonatal care. Such management has led to increased survival rates and decreased morbidity for these neonates.

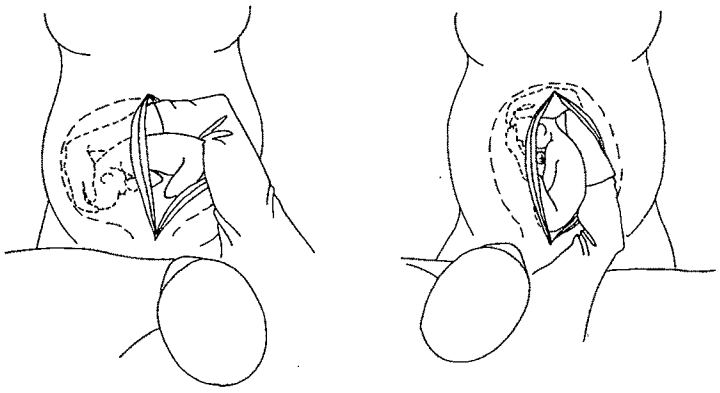

Fig. 1. The splint technique.

Cesarean section has been liberally used in an attempt to decrease intrapartum hypoxia and birth trauma. Mode of delivery of the fetus in cephalic presentation is controversial. Some advocate elective cesarean section of all very low birth weight fetuses while others believe that continuous electronic fetal heart rate monitoring allows early identification of the stressed fetus.[1] There is less controversy regarding the route of delivery in cases of malpresentation. Many authorities agree that cesarean section is indicated in such cases.[2]

A poorly developed lower uterine segment often makes a vertical uterine incision necessary (either low vertical, confined to the lower uterine segment, or classical, with the incision carried up to the uterine fundus). In spite of adequate uterine incision, difficulty in delivering the very low birth weight fetus presenting in a transverse lie or as a breech is sometimes encountered. Internal podalic version and breech extractions may be traumatic, even at cesarean section.[3] The very low birth weight fetus is particularly vulnerable to manipulative procedures, and excessive bruising may lead to significant blood loss and jaundice.[4] A technique that minimizes potential trauma with version and/or extraction techniques is described.

The technique consists of "splinting" the entire fetus, with the head held in the operator's hand, the trunk flat against the forearm, and the buttocks stabilized in the antecubital fossa (Fig. 1). In cases of a transverse lie, the entire fetus can be turned to either a cephalic or a breech presentation with subsequent atraumatic delivery. In my experience, the majority of these fetuses can be brought down as vertex presentations. Those who are brought down as a breech presentation or those who are de novo in breech presentations can be delivered up to the umbilicus, following which assisted breech delivery is performed. In many of my cases, however, the entire fetus was delivered while "splinted." Uterine relaxation with anesthetic agents was never required to accomplish the delivery. The technique has been used successfully in 25 cases.

The adult upper limb is uniquely suited for this type of technique, as the measurements of the hand and forearm correspond well to the measurements of the very low birth weight fetus. Fetal head circumference ranges from approximately 25 cm at 28 weeks' gestation to approximately 30 cm at 32 weeks' gestation. The crown-rump length of a fetus varies from 23 cm at 26 weeks' gestation to 28 cm at 32 weeks' gestation. In the author's case, the distance from the third terminal digit to the wrist is 19 cm, and that from the wrist to the antecubital fossa is 26 cm.

In summary, a technique to assist in the atraumatic delivery of the very low birth weight fetus at the time of cesarean section has been described which is applicable in cases of fetal malpresentation, either breech or transverse lie. A vertical uterine incision is often necessary. Intact amniotic membranes are helpful but not essential. Use of uterine relaxing anesthetic agents and subsequent risk of hemorrhage are avoided. If the technique fails, traditional management of uterine relaxation and version/extraction remains an option.

Cytosol estrogen receptor content of female parietal peritoneum

J. A. Hill, M.D., T. G. Muldoon, M.D., D. G. Gallup, M.D., W. A. Turner, M.D., R. A. Loy, M.D., and O. E. Talledo, M.D.

Augusta, Georgia

The ovarian and peritoneal mesothelium are believed to derive from the same embryonal coelomic epithelium. Neoplastic proliferation of these epithelia is sometimes grossly and histologically similar. Recently estrogen receptors have been identified in gynecologic neoplasms. With the use of standard techniques, the parietal peritoneum was assessed for estrogen receptor content in 17 women undergoing celiotomy for various reasons. All peritoneal specimens were negative for estrogen receptor content. This suggests a heterogeneous origin of the peritoneal surface epithelium and that peritoneum may not be müllerian in origin. (AM J OBSTET GYNECOL 1986;154:943-4.)

Key words: Estrogen receptors, parietal peritoneum

The mesothelium of the ovary and of the peritoneal cavity is believed to be the product of the same embryonal coelomic epithelium.[1] Peritoneal mesothelium may respond as ovarian mesothelium when appropriately stimulated.[2] Both benign and malignan gynecologic neoplasms contain estrogen receptor proteins. The purpose of this study was to determine whether estrogen receptor proteins are present in parietal peritoneum.

Material and methods

A 1 by 1 cm portion of normal parietal peritoneum was obtained in 17 women with various gynecologic pathologic conditions at celiotomy (Table I). The excised tissue was placed on dry ice and maintained at −20° C until assayed. For assay, the tissue was homogenized in a buffer consisting of 0.01 mol/L Tris, 1.5 mol/L sodium ethylenediaminetetraacetic acid, and 5 mmol/L dithiothreitol, pH 8.0, at 2° C. Cytosol was prepared as the 30-minute, 350,000 × g supernatant fraction of the homogenate. Cytosol estroger receptors were measured by saturation binding analysis, with a range of 0.2 to 5 nmol/L for radiolabeled estradiol. Radiolabeled estradiol was obtained from New England Nuclear, Boston, Massachusetts [(2,4 6,7-^{3}H) 17β-estradiol, 100 Ci/mmol]. It was purified before use by successive descending paper chromatography in two separate solvent systems. At each dosage, a duplicate assay was performed in the presence of a respective 100-fold molar excess of unlabeled 17β-estradiol to allow correction for nonspecific binding. Samples were incubated for 18 hours at 4° C to achieve binding equilibrium. Protamine sulfate precipitation was used to separate free from receptor-bound steroid. Specific binding was calculated as the difference between total and nonspecific values at each steroid level. The data were examined graphically by direct linear plot analysis for determination of the receptor-binding affinity and capacity of the tissue.

Results

The results are given in Table I. As shown, all specimens analyzed for cytosol estrogen receptor content were negative. In the five patients with serous cystadenocarcinoma, three were moderately differentiated and two were undifferentiated. The degree of tumor differentiation was not associated with the presence of estrogen receptors in normal uninvolved parietal peritoneum.

Comment

Our finding of no estrogen receptors in biopsy specimens of normal parietal peritoneum suggests that the parietal peritoneum may not be of müllerian origin.

Many undifferentiated ovarian cancers may not be gonadal in origin but rather are malignant mesotheliomas. These may arise primarily as tumors of the peritoneal surface, only secondarily involving the ovary.[2] In addition, endometriosis is believed to represent, for the most part, a metaplastic alteration of pelvic mesothelium mediated through sex steroid receptor proteins responsive to the endocrine milieu. It appears, therefore, that there is multipotentiality for

Table I. Summary of patient data

No. of patients	*Age (yr)*	*Pathologic diagnosis*	*Cytosol estrogen receptor content of normal peritoneum*
5	57-82	Stage III serous cystadenocarcinoma	Negative
1	36	Stage IB squamous cell carcinoma of cervix	Negative
1	27	Bilateral benign cystic teratoma	Negative
4	26-34	Endometriosis	Negative
1	50	Endometrial hyperplasia	Negative
5	34-54	Uterine leiomyoma	Negative

differentiation of müllerian oriented epithelium conditioned by embryonic origin.[1] This view may explain the occurrence of peritoneal tumor involvement without an obvious primary site of origin. This view, however, must be seriously questioned in light of our finding of no estrogen receptors in normal parietal peritoneum.

SYMPOSIUM

Symposium on Cefotetan

The following papers are selected from presentations given at an "Investigator's Symposium on Cefotetan," held on September 12-15, 1985.

Supported by an educational grant from Stuart Pharmaceuticals, Wilmington, Delaware.

Introduction

Those of us in the fields of infectious disease and surgery are now in the enviable position of having not a drug of choice but drugs of choice for prophylactic and therapeutic use against infection. A wide variety of antimicrobial agents is available with established efficacy and safety. Though they are not identical in their activity against various pathogens, none stands clearly above the others in terms of clinical usefulness.

As the papers presented at this symposium demonstrate, cefotetan, a new broad-spectrum, long-acting parenteral cephalosporin, can now be added to the array of effective agents. Cefotetan has microbiologic activity very similar to that of cefoxitin, inhibiting most Enterobacteriaceae, gram-positive cocci (except the Enterococcus), and anaerobes, including the troublesome *Bacteroides fragilis*. Cefotetan is as effective as cefoxitin in the settings described here and can be expected to be very useful in community-acquired intra-abdominal sepsis, propylaxis for colorectal, obstetric, and gynecologic procedures, abdominal trauma, and other settings.

In the current climate of health care, with roughly equivalent antibiotic agents, cost becomes an important issue. Because of its long half-life, cefotetan can be given twice per day in situations where other agents must be given three or four times per day. The cost savings that will result from a reduction in the number of administrations per day and the demands on nursing and pharmacy staff could be substantial. Therefore, based on my own research and that presented in this symposium, I expect that cefotetan will find an important role in prophylaxis and treatment of infection in situations where a broad spectrum antibiotic is needed.

Cefotetan in the treatment of obstetric and gynecologic infections

Alfred N. Poindexter III, M.D., Richard Sweet, M.D., and Marcella Ritter, M.D., Ph.D.
Houston, Texas, and San Francisco, California

The efficacy, tolerance, and safety of cefotetan—a new 7-α-methoxy cephalosporin—was assessed in controlled and uncontrolled evaluations involving 131 evaluable patients hospitalized with obstetric and gynecologic infections. The 99% satisfactory clinical response rate obtained with this drug was equivalent to that obtained with either moxalactam or cefoxitin, yet the mean amount of cefotetan given was lower than that of the other two drugs. Cefotetan was well tolerated and produced no major adverse reactions. In this era of Diagnosis Related Groups and cost containment, the twice-daily dosage schedule of cefotetan is a decided cost benefit. (AM J OBSTET GYNECOL 1986;154:946-50.)

Key words: Cefotetan, endometritis, pelvic inflammatory disease, antibiotics

In treating obstetric and gynecologic infections, an antibiotic with a broad spectrum of antibacterial activity and resistance to β-lactamase-producing species is often crucial to adequate patient response. Cefotetan—a new semisynthetic parenteral cephalosporin derivative and β-lactam antibiotic—has high resistance to hydrolysis by Richmond-Sykes types I, III, and IV β-lactamases of gram-negative bacteria.[1] This resistance is provided by the 7-α-methoxy group. The stability of cefotetan to β-lactamase is as high as that of cefoxitin; the two antibiotics have similar chemical structures.

Another notable feature of cefotetan is an elimination half-life of >3 hours, which is longer than that of most commercially available cephalosporins. Normal volunteers had high plasma levels of cefotetan after receiving either 500 mg or 1000 mg every 12 hours.[2] Its relatively long half-life and good antimicrobial activity in treating gynecologic infections—frequently involving polymicrobial combinations of anaerobes and aerobes—make cefotetan an ideal antibiotic for hospitalized patients requiring more than 48 hours of intravenous treatment. Twice-daily administration of a single agent such as cefotetan is of decided advantage in this era of Diagnosis Related Groups, prospective payment schedules, and cost containment.

In an in vitro study involving 1063 gram-negative isolates, concentrations of cefotetan ranging from 0.007 to 3.2 mg/L inhibited 90% of all isolates of *Escherichia coli, Klebsiella* and multiresistant strains of this organism, *Proteus mirabilis, P. vulgaris, Providencia rettgeri, P. stuartii, Serratia marcescens,* and *Citrobacter freundii.*[3] Cefotetan is as active as moxalactam, a related cephalosporin, against gram-positive cocci. Cefotetan has moderate activity against *Staphylococcus aureus* and *Streptococcus pyogenes.*[3]

In another in vitro study involving 12,260 isolates, the inhibitory spectrum of cefotetan paralleled the spectra of the newest generaton of cephamycins and exceeded those of cefoxitin and cefamandole.[1] Cefotetan has high activity against *Neisseric gonorrhoeae.*[4]

All studies have shown that cefotetan is either inactive or has very poor activity against *Pseudomonas aeruginosa, Acinetobacter* organisms, enterococci, and methicillin-resistant *S. aureus.* Cefotetan is active against *Serratia* and *Providencia* organisms and Enterobacteriaceae—three of the problem organisms of hospitals.

To obtain additional evidence on the efficacy, tolerance, and safety of twice-daily intravenously administered cefotetan in treating obstetric and gynecologic infections, controlled and uncontrolled studies were conducted with cefotetan.

Materal and methods

The study protocol was reviewed and approved by the Institutional Review Board for Experiments Involving Human Subjects. Written informed consent was obtained from all patients.

Hospitalized patients originally seen in the emergency room for complaints related to acute pelvic infection were entered into the studies. These patients had either known or suspected bacterial disease and were considered likely to meet all study criteria. No patient was entered into evaluation who was pregnant or breast-feeding, had a history of penicillin allergy, or received antibiotics immediately before hospital admission. The study populations were primarily young and nonwhite; many of the patients had underlying

and hepatic parameters. When treatment was prolonged, laboratory tests of these parameters were repeated at least weekly. Follow-up was made when these test results were abnormal. Patients were assessed daily for local tolerance to the intravenous injections and for adverse reactions to the drug. The pharmacokinetics of cefotetan were evaluated by determining peak and trough serum levels and urine concentrations, with use of plasma and urine specimens obtained on day 2, 3, or 4 of the study.

Both clinical and bacteriologic responses to treatment were assessed. Clinical response was considered satisfactory if local or systemic signs of infection had disappeared or were substantially improved after treatment. Bacteriologic response was determined by comparing isolates obtained before and after therapy and was considered satisfactory if causative pathogens were eradicated or if a good clinical response was obtained despite the presence of a new pathogen.

Laboratory data were analyzed by linear regression coefficients and slopes, with use of drug therapy as the independent variable. Missing patient data were eliminated from statistical analysis.

Results

A total of 118 recipients of cefotetan, 34 in the controlled study and 84 in the uncontrolled study, were judged evaluable for efficacy, while all recipients of this drug were used in the analyses of laboratory values and adverse effects. The pelvic infections of evaluable cefotetan recipients were diagnosed as endometritis (59 cases), pelvic inflammatory disease (52 cases), salpingitis (two cases), or "other" (five cases). Sixty-one evaluable cefotetan recipients had community-acquired infections; 53, hospital-acquired infections; 4, infections of unknown source (Table II).

In the controlled study, 34 evaluable patients received 2 gm of cefotetan every 12 hours; eight patients, 2 gm of moxalactam every 8 hours; four patients, 2 gm of cefoxitin every 8 hours; and one patient, 1 gm of cefoxitin every 8 hours. In the uncontrolled study of cefotetan, 54 evaluable patients received 2 gm every 12 hours, and 30 evaluable patients received 3 gm every 12 hours. Of the overall 118 evaluable recipients of cefotetan, 88 received 2 gm every 12 hours and 30 received 3 gm every 12 hours. In the controlled eval-

Total	157		154		149	

uations the mean durations of therapy were 5.9 days for cefotetan recipients, 5.8 days for moxalactam recipients, and 7.2 days for cefoxitin recipients. The mean duration of cefotetan therapy in the uncontrolled trial was 5.9 days. For the two cefotetan studies combined, the mean duration of treatment was also 5.9 days. In either evaluation of cefotetan, the mean amount of this drug given (21.5 gm in the controlled study, 25.2 gm in the uncontrolled study, 24.1 gm overall) was less than that of moxalactam (31 gm) or cefoxitin (36 gm).

Ninety-nine percent of evaluable cefotetan recipients (n = 118) had a satisfactory clinical response to treatment. The satisfactory clinical response to treatment was 100% for recipients of either moxalactam (n = 8) or cefoxitin (n = 5). There were no statistically significant differences between these clinical response levels (Tables III, IV, and V).

Eleven (4%) of 247 isolates showed an unsatisfactory bacteriologic response to cefotetan therapy (Table VI). Among cefotetan recipients the primary pathogen isolated was *N. gonorrhoeae* (39 isolates). Other isolates of prominence from these patients included *Streptococcus* species (34 isolates), *E. coli* (24 isolates), *S. agalactiae* (23 isolates), and *S. epidermidis* (17 isolates).

Adverse signs and symptoms in cefotetan- or comparator drug–treated patients were infrequent and generally mild in severity. In the controlled protocol, two patients had drug-related adverse signs and symptoms. One cefotetan-treated patient had a report of

monilial vaginitis, and a moxalactam-treated patient had a report of phlebitis. There were 10 reports of drug-related adverse signs and symptoms in six cefotetan-treated patients in the uncontrolled protocol. The 10 reports included serum glutamic-oxaloacetic transaminase increase, serum glutamic-pyruvic transaminase increase, phlebitis, urticaria, rash, papular rash, tachycardia, dyspnea, nausea, and monilial vaginitis.

Plasma and urine assay data are summarized in Table VII.

Comment

These evaluations demonstrated that twice-daily administration of intravenous cefotetan is highly efficacious in treating obstetric and gynecologic infections of hopsitalized patients. Cefotetan was at least as successful as moxalactam and cefoxitin in the comparative evaluations of clinical response. Moreover, the mean amount of cefotetan used was less than that of either moxalactam or cefoxitin—further indicating the high efficacy of cefotetan.

The controlled and uncontrolled evaluations of cefotetan also affirmed the safety of this drug.

We found no statistically significant changes in urinary levels of cefotetan for any of the days measured.

In conclusion, twice-daily administration of intravenous cefotetan is a highly efficacious means of treating obstetric and gynecologic infections of hospitalized patients. The drug, which we found to be safe and well tolerated, can be administered less frequently and at lower doses than can moxalactam and cefoxitin, while still obtaining at least equivalent clinical results.

Comparison of cefotetan and cefoxitin as prophylaxis in cesarean section

Michael W. Varner, M.D., Carl P. Weiner, M.D., C. Rosemarie Petzold, B.S., and Rudolph P. Galask, M.D.

Iowa City, Iowa

A study comparing the efficacy of cefotetan versus cefoxitin for prophylaxis in patients undergoing cesarean section was carried out at the University of Iowa. After institutional review, 36 subjects who met the study criteria and agreed to participate were entered into the study; of these, 29 were evaluable for efficacy. Twenty subjects received a single 2 gm dose of cefotetan, and nine subjects received three 2 gm doses each of cefoxitin. Both antibiotics were administered intravenously at the time the umbilical cord was clamped. The subsequent doses of cefoxitin were given intravenously at four and eight hours after the initial dose. Clinical and bacteriologic responses were evaluated; there were no statistically significant differences between the two groups, and both antibiotics provided effective prophylaxis against infection. It appears that cefotetan is a satisfactory antibiotic choice for cesarean section prophylaxis. Further, in this small study it appears that a single dose of cefotetan is as effective as three doses of cefoxitin. This implies that cefotetan would not only decrease administration time and supplies but would decrease the cost to the patient while maintaining very acceptable infection rates. (Am J Obstet Gynecol 1986;154:951-4.)

Key words: Cefotetan, cesarean section, antibiotic prophylaxis

The past two decades have seen an increase in the incidence of cesarean sections. Although this increased cesarean section rate has been associated with diminished perinatal mortality, it has also been associated with an increase in maternal postoperative infections.[1] The reported incidence of endometritis occurring after primary cesarean section ranges from 29%[2] to 85%,[3] which is five to 15 times the rate observed in similar populations delivered vaginally. The majority of such obstetric postoperative infections are polymicrobial in origin and involve organisms indigenous to the reproductive tract. The most commonly isolated organisms are the aerobic and anaerobic streptococci, the aerobic gram-negative rods (the most common of which is *Escherichia coli*), and the anaerobic gram-negative rods (including *Bacteroides fragilis*).[4]

Although the use of prophylactic antibiotics for patients undergoing cesarean section has only been studied for 15 to 20 years, it has been unequivocally shown to be of benefit.[5] Whereas in the past antibiotics were administered preoperatively, they are now administered intraoperatively immediately following delivery and clamping of the umbilical cord. Multiple antibiotic regimens have been used, almost all with some success.[6] A number of drugs are currently approved for cesarean section prophylaxis by the Food and Drug Administration, and all currently require multiple administration.

Cefotetan is a new broad-spectrum cephalosporin antibiotic that is very resistant to gram-negative β-lactamases. It is active against many of the organisms commonly encountered in post–cesarean section infections.[7] Because of its broad spectrum of activity, its reported high concentration in uterine tissue, and its extended mean elimination half-life, cefotetan could be a potentially useful agent in the prevention of post–cesarean section infections. The decision was therefore made to compare cefotetan in a randomized prospective blinded fashion against a commonly used and approved antibiotic (cefoxitin sodium). The objectives of the study were (1) to evaluate the safety, tolerance, and prophylactic effectiveness of cefotetan in reducing the incidence of postoperative infections associated with cesarean section and (2) to obtain information on plasma levels of cefotetan after intravenous administration.

Material and methods

The study protocol was reviewed and approved by the University of Iowa Hospitals and Clinics Institutional Review Board for Experiments Involving Human Subjects. Written informed consent was obtained from all patients.

Inclusion criteria were considered for all hospitalized adult female patients scheduled to undergo primary or repeat cesarean section. These criteria included age of 15 to 50 years, a willingness to forego breast-feeding

for at least 48 hours after antibiotic administration, and the absence of clinical or bacteriologic evidence of infection. Asymptomatic bacteriuria was not considered an exclusion.

Exclusion criteria included (1) an oral temperature of 100.4° F (38° C) or greater within 24 hours before surgery, (2) a history of immediate hypersensitivity reaction or other adverse reaction to penicillin or to cephalosporin-type agents, (3) known or suspected significant renal function impairment as manifested by a serum creatinine level of 2.5 mg/100 ml or greater, (4) the presence of an associated serious underlying disease or rapidly fatal condition that would make it unlikely that treatment in the study or follow-up could be completed, (5) an identifiable risk of life-threatening pseudomonas disease (for example, patient with acute leukemia or granulocytopenia), (6) the presence of obvious amnionitis as manifested by an increased white blood cell count and/or uterine tenderness (this group of patients was excluded even if afebrile), and (7) subjects receiving an antibiotic agent within 2 weeks of entering the study.

After informed consent was given, patients were randomized to receive either 2 gm of cefotetan intravenously immediately after clamping of the umbilical cord, or 2 gm of cefoxitin intravenously immediately after cord clamping. Patients in the latter group also received 2 gm of cefoxitin intravenously at 4 and 8 hours post partum. Randomization was accomplished with use of an allocation schedule provided by the Biostatistics Department of Stuart Pharmaceuticals Inc. A total of 36 patients were assigned to cefotetan or cefoxitin in a 2:1 ratio with the intent of accumulating a total of 30 evaluable patients. No other antibiotics were administered subsequently unless they were considered clinically indicated by the attending physicians.

Table III. Preoperative laboratory values*—evaluable patients

	Cefotetan (n = 20)	*Cefoxitin (n = 9)*

*All values expressed as mean values.

†Indicates statistically significant difference ($p<0.05$, Wilcoxon rank sum test).

Before surgery, all patients were evaluated with clean-catch midstream urine cultures, complete blood counts, prothrombin times, and serum chemistry studies to measure hepatic and renal function. Preoperative transvaginal cervical cultures were obtained only in women with premature rupture of the membranes. Intraoperative transabdominal cultures were obtained from the endocervix and abdominal incision. Plasma specimens were obtained between 1 and 2 hours postoperatively to assay concentrations of cefotetan. All laboratory studies were repeated at 24 hours postoperatively, and all patients were evaluated daily with particular attention to wound grading and possible adverse reactions. Appropriate material for culture was obtained from any subject who subsequently developed an infection. All patients received a final evaluation at 7 to 10 days after discharge.

Criteria for early discontinuation included development of any serious medical condition that would make it unwise in the opinion of the investigators to continue, presence of a serious or alarming adverse reaction, an opinion of the investigator that it was in the best interest of the patient to withdraw, or the patient's desire to withdraw from the study.

Response criteria were evaluated both on clinical and bacteriologic grounds. Clinical success was defined as lack of signs or symptoms of infection. Clinical failure was defined as development of signs or symptoms of infection, including fever, urinary tract infection, wound infection, parametritis/pelvic cellulitis, endometritis, pelvic abscess, septic pelvic thrombophlebitis, or bacteremia. Bacteriologic success was defined as no

evidence of bacteriologic pathogens in all postoperative cultures. An unsuccessful bacteriologic response was defined as the presence of $>10^5$ organisms per milliliter in a urine culture, two consecutive positive blood cultures, or the presence of potentially significant pathogens on subsequent clinically indicated cultures.

Statistical evaluation for continuous measures was accomplished with use of the Wilcoxon rank sum test. For categorized data the χ^2 analysis was used. A p value of 0.05 was assigned for minimal statistical significance.

Results

The total number of patients randomized in this study was 36, of whom 29 were evaluable for efficacy. The indications for exclusion are presented in Table I.

The demographic characteristics of the evaluable patients are presented in Table II. As can be seen, the two groups were not significantly different in any of these respects, although there were relatively higher frequencies of term delivery and primary cesarean section in the cefotetan group. The preoperative laboratory values are demonstrated in Table III. These are similar in both groups except for alkaline phosphatase. The postoperative laboratory parameters (Table IV) revealed no persistent difference in alkaline phosphatase values.

Clinical response was evaluated in both groups, and a statistical difference was not found (Table V). This included increase above pretreatment temperature, postoperative hospitalization in days, and wound grading as defined by Karl et al.[8]

Bacteriologic response was also evaluated and was not significantly different in either group (Table VI). Both bacteriologic failures in the cefotetan group involved endometrial cultures revealing enterococci in patients with clinical endometritis.

Only one adverse sign or symptom was seen in the entire study population (Table VII). A patient who received cefoxitin developed pruritus within 24 hours after drug administration. This resolved spontaneously without treatment. No adverse signs or symptoms were seen in any patient receiving cefotetan.

Plasma cefotetan concentrations were obtained for 23 patients postoperatively and are shown in Table VIII, which demonstrates adequate antibacterial levels.

Comment

No serious side effects were noted in any of the patients participating in this study. Although the cefotetan group did have significantly higher preoperative serum alkaline phosphatase values, we do not believe this represents a clinically significant difference, since the other serum chemistry values reflecting hepatic function were similar in both groups. During pregnancy, alkaline phosphatase is produced by the placenta, and larger, more mature babies tend to have larger placentas. Because there were relatively more term deliveries in the cefotetan group, we were not surprised to see a relatively greater increase in alkaline phosphatase in this group. Alkaline phosphatase values were not different at the time of postoperative laboratory assessment.

The current study represents the first comparison of

a single-dose prophylactic antibiotic compared directly to a currently approved three-dose regimen. No statistically significant differences were found for any of the major variables examined. This suggests that cefotetan (2 gm intravenously in a single dose) may be as satisfactory a choice for post–cesarean section infection prophylaxis as cefoxitin (2 gm intravenously in three doses), especially if it can be administered with less expense and possibility for error in administration. Further studies with larger numbers will be required to adequately address these issues.

This study also shows that cefotetan has sufficiently high serum levels for several hours in women undergoing cesarean section, which supports its potential use as a single-dose prophylactic agent.

It was the impressionn of the authors that cefotetan allowed decreased administration time, fewer supplies, and therefore a decrease in cost, while maintaining good prophylaxis against infection. Further evaluation of this would seem warranted on the basis of these findings.

Single-dose cefotetan versus multidose cefoxitin for prophylaxis in cesarean section in high-risk patients

James A. McGregor, M.D., C.M., Janice I. French, C.N.M., M.S., and Edgar Makowski, M.D.

Denver, Colorado

A prospective, randomized, open trial of a single intravenous dose of a new broad-spectrum and long-acting cephalosporin was compared with the effect of three doses of cefoxitin in a group of 70 women undergoing cesarean section who were at high risk for postoperative endomyometritis and wound infection. All patients either had ruptured membranes or were in active labor, or both, without clinically detectable chorioamnionitis at the time of prophylaxis. Forty-six women received a single 2 gm dose of cefotetan and 24 received 2 gm of cefoxitin every 4 hours to complete a three-dose regimen. Outcomes of infectious febrile morbidity due to endomyometritis (15% versus 8%), wound erythema (4% versus 12%), and other parameters were similar for cefotetan and cefoxitin, respectively. Both agents were well tolerated in this high-risk population. Within the limits of this study, single-dose cefotetan chemoprophylaxis appears to be comparable to multidose cefoxitin administration in reducing morbidity in operative site infections after cesarean section. (Am J Obstet Gynecol 1986;154:955-60.)

Key words: Cefotetan, cesarean section, endomyometritis, postoperative infection

Use of perioperative systemic antibiotic chemoprophylaxis in women who are at increased risk for postoperative infection after cesarean section has proved effective and is an increasingly accepted practice.[1, 2] Further understanding of the optimum use of chemoprophylaxis regimens that provide maximum desired effect while engendering minimum iatrogenic morbidity and costs is required.[6] Major issues requiring continued study include (1) stratification of patients at risk for infection and (2) optimization of cost-effective use and ease of administration in patients in whom antibiotic prophylaxis is indicated. Studies of clinical characteristics of women at risk for postoperative infection after cesarean section identify similar findings in a variety of settings. These include labor, ruptured membranes, and low socioeconomic status in antibiotic-treated, placebo-treated, and untreated women.[3-5] Differentiation of other host factors, including qualitative and quantitative aspects of microbiologic colonization and/or infection at the time of operation, remains to be more fully elucidated.

Much interest is presently focused on practical aspects of chemoprophylaxis administration, including the benefits of single-dose administration in comparison with multidose chemoprophylaxis.[6] Recently developed antimicrobial agents possess both antimicrobial coverage (most aerobic and anaerobic lower genital tract microorganisms) and pharmacokinetic properties that allow for extended serum and tissue levels after single administration.[7] In order to evaluate a new broad-spectrum cephalosporin that possesses these attributes in preventing post–cesarean section infection, we evaluated cefotetan in a randomized, prospective trial of prevention of postoperative infection in comparison with a three-dose regimen of cefoxitin, an established agent in this setting.

Material and methods

This study was performed at University Hospital, University of Colorado Health Sciences Center, in Denver, Colorado. The study protocol was reviewed and approved by the Institutional Review Board for Experiments Involving Human Subjects. Patients who were to have cesarean section in the presence of ruptured membranes and/or labor and who denied allergy to penicillin or cephalosporin-like agents were asked to sign an informed consent before entering the study. Treatment was assigned in a ratio of 2:1 for cefotetan versus cefoxitin by use of a blinded, computer-generated, randomized schedule, which was kept in the central pharmacy. The prophylactic regimens were either a single administration of a 2 gm dose of cefotetan given intravenously immediately after cord clamping or a similarly administered 2 gm dose of cefoxitin followed by two further intravenous doses at 4 and 8 hours after operation.

The criteria for exclusion were as follows: an oral temperature ≥100.4° F (38° C) within 24 hours before operation; history of an immediate hypersensi-

ease; obvious amnionitis manifested by increased white blood cell count or uterine tenderness, even if the patients were afebrile; administration of any antibiotic agents within 2 weeks of starting this prophylactic regimen.

All patients had a complete blood count, differential count, and platelet count, and determination of prothrombin time, blood urea nitrogen, creatinine, electrolyte, and liver enzyme blood levels, as well as urine culture and urinalysis, with specimens obtained preoperatively from the Foley catheter. These tests were repeated approximately 24 hours later. Cervical cultures for aerobic and anaerobic bacteria were obtained preoperatively. Similar cultures were obtained from the lower uterine segment subsequent to the delivery of uterine contents and from the subcutaneous wound at the time of skin closure. Specimens were collected in Anaerobic Transport Tubes (BBL, Cockeysville, Maryland) and immediately taken to the University Hospital Microbiology Laboratory where they were inoculated with a variety of standard aerobic or anaerobic media. Aerobic microorganisms were recovered by plating specimens on 5% sheep blood agar, chocolate agar, modified Martin-Lewis agar, and MacConkey's agar with all plates incubated in 5% carbon dioxide environment at 35° C. Anaerobic microorganisms were cultured by plating on anaerobic Brucella agar plates containing 5% sheep blood and supplemented with hemin and vitamin K_1. In addition, one tube of fluid thioglycollate with supplemented hemin and vitamin K_1 was inoculated. Plates were placed in an anaerobic environment with the use of a Gas-Pak generator system (Bioquest, BBL) and incubated at 35° C. Aerobic cultures were read at 24 and 48 hours and reported semiquantitatively. Anaerobic cultures were examined at 2 days for plates and 7 days for broth. Established microbiologic techniques were used to identify both aerobic and anaerobic microorganisms.[8] Sensitivities of aerobic microorganisms were determined by Kirby-Bauer techniques.[8]

*One patient in cefotetan group was diagnosed as having endomyometritis and wound infection.

Standardized forms were used to collect demographic, clinical, laboratory, microbiologic, and postoperative outcome data. Patients were evaluated twice daily during hospitalization. Any patient who developed an oral temperature ≥38° C on two occasions at least 6 hours apart was carefully evaluated with standard techniques for the cause of febrile morbidity.[9, 10] Standard criteria for determining postoperative infectious morbidity were used.[9] Postoperative endomyometritis was defined as fever ≥38° C with uterine tenderness and a positive endometrial culture in the absence of any other cause of infectious morbidity. Any patient with febrile morbidity of any cause had a repeat blood count and differential count as well as a urine culture and repeat endometrial culture of a specimen taken with a double-lumen catheter (Uterine Sampling Device, Medi-Tech, Watertown, Massachusetts). Roentgenographic and other diagnostic procedures were performed if clinically indicated. The usual treatment for postoperative endomyometritis despite chemoprophylaxis was a combination of ampicillin with genta-

micin or these drugs plus clindamycin or gentamicin and clindamycin, all given intravenously. Data were analyzed by the computer programs of the Statistical Package for the Social Sciences on an IBM XT computer. Standard statistical methods for analysis of variance, Student's t test and χ^2 for parametric data, and Mann-Whitney U testing for nonparametric data were used.

Results

Seventy patients underwent cesarean section and were evaluated. Forty-six received a single 2 gm dose of cefotetan and 24 received three 2 gm doses of cefoxitin. There were no significant differences among treatment groups for age, race, socioeconomic status (as measured by method of payment), or individual medical characteristics as noted in Table I. Various risk factors for postoperative infectious morbidity were evaluated. There were no significant differences between the treatment groups in occurrence of these factors, other than the presence of ruptured membranes, as noted in Table II. Operative indications are listed in Table III. The similarity between the treatment groups allows for comparison of outcomes. Analysis of the effect of ruptured membranes for each treatment group was carried out separately (Table IV).

Comparative results for postoperative infectious morbidity are summarized in Tables IV and V. There were no significant differences between the test regimens in the occurrence of febrile morbidity, endomyometritis, wound infection, wound erythema, urinary tract infection, or other study parameters. The presence of endomyometritis, wound infection, or wound erythema did not differ significantly with membrane status for either treatment group (Table IV). There were small numbers of infectious complications in both groups.

Preoperative cultures revealed the presence of nor-

Two additional patients had wound infections. One of these had group D streptococci isolated from the cervix but not the uterus or incision. Endometrial cultures were not obtained from patients with wound infections, unless uterine symptoms were present.

mal cervical-vaginal microorganisms at the cervix or no growth in all women (Table VI). Microorganisms (one to four isolates) were recovered from the lower uterine segment in 53 of 70 procedures (75.7%). A total of 98 isolates was recovered from the lower uterine segment from 53 patients (1.8 isolates each). One or more (one to three) microorganisms were recovered from subcutaneous tissue from 55 patients (78.3%) treated with either medication. Microorganisms isolated before, during, and after operation from patients who developed postoperative endomyometritis are listed in Table VII. All of these microorganisms were susceptible to both cefoxitin and cefotetan except group D streptococcus. All patients with postoperative morbidity due to endomyometritis responded to treatment.

No patient developed a pelvic abscess, and there were no episodes of pelvic thrombophlebitis. There were no untoward side effects from either regimen, and laboratory tests revealed no significant alterations. Postpartum clinical and chart review revealed no delayed infectious morbidity at 6 weeks other than a single case of endomyometritis in the cefotetan group and a single wound infection in the cefoxitin group.

Comment

Development of operative site infection subsequent to cesarean section depends on several factors that include the number of microorganisms within the wound, virulence of these microorganisms, presence of substrate to support bacterial growth, and the efficacy of host factors in dealing with these microorganisms.[11] Cesarean section predisposes patients to significant risks of infectious morbidity because of the "clean-contaminated" and relatively traumatic nature of the procedure. The presence of potentially pathogenic cervical-vaginal microorganisms within the lower uterine segment and amniotic fluid at the time of cesarean section in women in labor or with ruptured or even intact membranes has been demonstrated.[12, 13] In the process of surgical entry of the uterine cavity and during the subsequent closure, these microorganisms gain access to the myometrial incision as well as the abdominal wound as shown here. The relatively extensive suturing associated with most cesarean section closure techniques assures that there is devitalized tissue along with considerable foreign suture material that alters local homeostasis and impairs host defenses.

Cumulatively, these processes lead to rates of postoperative endomyometritis as high as 85% to 95% after cesarean section in high-risk patients.[5, 12, 14] Potentially lethal complications, such as septic shock, abscess formation, and pelvic thrombophlebitis, may occur in up to one of three high-risk women.[14] The antibiotic treatment results in this study are comparable to those with similar agents in placebo-controlled studies of chemoprophylaxis. This study demonstrates the comparable efficacy and safety of cefotetan when compared with cefoxitin. While costs were not detailed in this analysis, it is reasonable to suppose that a single-dose regimen would be less expensive than a three-dose regimen if these agents are comparably priced. Similarly, a single exposure to an antimicrobial agent may be less likely than three consecutive doses to cause selective pressure on endogenous microflora. The results of this small study are compatible with cefotetan's broad-spectrum and extended antimicrobial activity. We suggest that cefotetan and cefoxitin are comparable in terms of efficacy and safety, but cefotetan possesses the relative advantage of being effective after a single administration in high-risk cesarean section patients.

Cefotetan versus cefoxitin as prophylaxis in hysterectomy

James. W. Orr, Jr., M.D.,* R. Edward Varner, M.D., Larry C. Kilgore, M.D., Robert C. Holloway, M.D., and Mary McDiarmid, R.N.

Birmingham, Alabama

Seventy hospitalized women were entered into an open, randomized, parallel study of antimicrobial prophylaxis for abdominal and vaginal hysterectomy with the use of either cefotetan, a new long-acting cephalosporin, or cefoxitin. Ninety-four percent of cefotetan recipients and 83% of cefoxitin recipients did not develop clinical signs or symptoms of infection. The satisfactory bacteriologic response rates were significantly different: 91% satisfactory (43 of 47 patients) for cefotetan and 74% satisfactory (17 of 23 patients) for cefoxitin. The two treatment groups demonstrated no significant differences in postoperative temperature changes, duration of hospitalization, or grading of surgical wounds. Neither drug was associated with significant side effects. (Am J Obstet Gynecol 1986;154:960-3.)

Key words: Cefotetan, hysterectomy, antibiotic prophylaxis, postoperative infection

Prophylaxis with parenteral antibiotics has been reported to reduce the incidence of infectious morbidity in gynecologic surgical procedures. Although individual risks of pelvic infection may be related to numerous variables, such as age, duration of operation, indication for operation, and use of vasoconstrictors,[1,2] the efficacy of antimicrobial prophylaxis during vaginal surgical procedures is detailed in almost all reports. The efficacy of such prophylaxis during abdominal operations is less well established.[3]

This report details a randomized prospective comparison of the safety, tolerance, and effectiveness of a single dose of cefotetan, a new, broad-spectrum, long-acting cephalosporin, and of multiple (three-dose) perioperative doses of cefoxitin.

Material and methods

The study protocol was reviewed and approved by the University of Alabama Medical Center Institutional Review Board for Experiments Involving Human Subjects. Written informed consent was obtained from all patients.

Included in this protocol, carried out during a 14-month period, were 79 hospitalized women undergoing nonradical abdominal or vaginal hysterectomy with or without colporrhaphy. Patients were excluded from the trial on the following bases: an oral temperature of ≥100.4° F during the 24 hours preceding operation; a history of allergy or adverse reactions to pen-

Table I. Patient population

	Cefotetan	*Cefoxitin*
No. of patients	54	25
Age (yr)		
Mean	36.7	35.8
Range	22-76	23-57
Race (% Caucasian)	50	40
Vaginal hysterectomy (n and %)	38 (70)	19 (66)
Abdominal hysterectomy (n and %)	16 (30)	6 (24)

icillins or cephalosporins; renal function impairment (serum creatinine >2.5 mg/100 ml); severe hepatic, hematologic, or other systemic disorders; a history of chronic pelvic infection; a history of pelvic operation within the 2 weeks preceding hysterectomy; treatment with antibiotics within 1 week of starting prophylactic treatment. Also excluded were all patients who had urinary tract infections ($>10^5$ bacteria) on admission.

The 79 study subjects were randomized to a treatment group in a ratio of two cefotetan recipients to one cefoxitin recipient. Fifty-four patients received a 2 gm intravenous injection of cefotetan 30 to 60 minutes before operation. Twenty patients received a 2 gm intravenous injection of cefoxitin 30 to 60 minutes before the initial incision and two 2 gm doses administered intramuscularly at 6 hour intervals after operation.

Urine and uterocervical cultures were obtained before treatment. Evaluation of urine cultures included bacterial isolation, identification, and a quantitative count, as well as sensitivity testing. Uterocervical culture evaluation included bacterial isolation, identification, and sensitivity testing. Specimens were transported in anaerobic specimen containers (Vacutainer Anaerobic Specimen Collector, Becton Dickinson and Company, Rutherford, New Jersey) and were plated on selective or nonselective media within 4 hours of collection. All plates were incubated at 35° C at appropriate atmospheric conditions: chocolate agar in 5% to 10% carbon dioxide, blood agar and eosin methylene blue agar in an anaerobic environment (Gas Pak Anaerobe System, BBL, Cockeysville, Maryland). Aerobic organisms were identified by conventional microbiological methods, including the API 20E system for gram-negative bacteria (Analytab Products, Plainview, New York). Anaerobic organisms were identified by the API 20A anaerobe system (Analytab Products).

The antibiotic sensitivity testing of aerobic organisms was determined by the standard disk diffusion method with the use of a 30 mcg cefotetan disk.

During operation, plasma and uterine tissue specimens were collected and frozen for the determination of cefotetan levels. Cultures of hysterectomy abdominal and vaginal wounds were obtained at the time of closure; aerobic and anaerobic pathogens were isolated, identified, and tested for sensitivity as described.

Twenty-four hours after operation, urine and vaginal cuff cultures were repeated. Specimens for culture were also collected from other sites (incision) or when evidence of infection existed. On the third postoperative day, another culture of the vaginal cuff was obtained.

Table III. Comparison of the clinical and bacteriologic response rates

	Clinical response (%)	*Bacteriologic response (%)*
Cefotetan	94	91
Cefoxitin	83	74

Through daily clinical assessment of all patients, surgical wounds were graded for detection of infection, adverse systemic effects, and local intolerance.

Before treatment, laboratory testing for hematologic, hepatic, and renal parameters was carried out. Laboratory assessment was repeated before discharge or, if hospitalization was prolonged, performed weekly. Seven to 10 days after discharge, each patient received a final evaluation. Changes in laboratory values and temperatures were analyzed for all treated patients.

The clinical response was considered successful when no signs or symptoms of infection developed during the postoperative period. The bacteriologic response was considered satisfactory when predischarge cultures contained no evidence of resistant bacteriologic pathogens.

Results

One of three surgeons performed or assisted at each of the procedures. Preoperative hospitalization (<2 days) was minimized; preoperative hair removal, if necessary, was performed just before operation. No drains were used, and small polyglycolic acid sutures were used in 80% of patients.

Analysis indicated that the desired 2:1 randomization ratio (54 cefotetan, 23 cefoxitin) was obtained. Forty-seven of the cefotetan recipients (15 abdominal hysterectomy patients and 32 vaginal hysterectomy patients) and 23 of the cefoxitin recipients (5 abdominal hysterectomy patients and 18 vaginal hysterectomy patients) were evaluable. Nine patients (seven cefotetan, two cefoxitin) were excluded from evaluation of clinical

*Some patients had more than one adverse reaction.

or bacteriologic response: six who received nonstudy antimicrobials after operation, two who were entered in an investigational pain study, and one who had positive pretreatment urine cultures. All 79 study subjects were included in the analyses of laboratory parameters, postoperative temperature, duration of hospitalization, and adverse signs and symptoms. Surgical wounds were graded only in those patients undergoing abdominal hysterectomy.

There were no statistically significant differences between the two treatment groups in the categories of race, age, diagnosis, surgical procedure, general patient condition, or serum creatinine levels (Table I). Indications for operation were not different (Table II). The cefotetan group had, on the average, a lower preoperative temperature (98.4° versus 98.7° F) and a higher preoperative alkaline phosphatase level (72.9 versus 62.72 mU/ml). Although these were statistically significant differences, both factors were well within the normal range.

In 94% of cefotetan recipients and 83% of cefoxitin recipients, no clinical signs or symptoms of infection developed (Table III). Among patients receiving cefotetan, two (4.2%) developed pelvic cellulitis and one (2.1%) developed bacteriologic evidence of urinary infection. Among cefoxitin patients, one (4.3%) required additional antibiotics for postoperative cellulitis and three (13%) had bacteriologic evidence of a postoperative urinary infection. No patients developed abdominal wound infection, pelvic abscess, septic pelvic thrombophlebitis, bacteremia, or pneumonia.

There were no statistically significant differences in postoperative temperature, duration of hospitalization, or grading of surgical wounds. Forty-three of 47 (91%) evaluable patients who received cefotetan and 17 of 23 (74%) cefoxitin recipients had satisfactory bacteriologic responses (Table III). This difference was statistically significant (χ^2 = $p < 0.05$).

A total of 39 patients (28 cefotetan 11 cefoxitin) reported adverse signs and symptoms. Of the 57 reported adverse effects (41 cefotetan, 16 cefoxitin), none were considered to be related to treatment (Table IV).

Median plasma cefotetan concentration, as measured 65 minutes after a 2 gm intravenous administration, was 149.5 μg/ml (range 1.7 to 215 μg/ml). The median uterine tissue concentration of cefotetan, as measured at a median time of 59 minutes, was 89.0 μg/gm (range 3.5 to 216 μg/gm).

Comment

Cefotetan, a semisynthetic derivative of oganomycin G produced by *Streptomyces oganonesis*, is stable to β-lactamases of gram-negative bacteria and is particularly active against *Escherichia coli, Hemophilus influenzae, Kleb-*

siella sp., *Proteus mirabilis,* and indole-positive *Proteus.* Like many other cephalosporins, cefotetan is not active against *Streptococcus faecalis* or *Pseudomonas.*[4]

In vitro testing for cefotetan activity against anaerobic bacteria that complicate gynecologic operations indicated that for 90% of strains of anaerobic gram-positive pathogens of the *Peptococcus* and *Peptostreptococcus* species, the minimum inhibitory concentration was 2 mcg/ml.[5] Moreover, 83% of *Bacteroides fragilis* isolates were inhibited by concentrations of 8 mcg/ml or less of cefotetan.[5] However, the National Committee on Clinical Laboratory Standards recommendations have set the breakpoint of cefotetan at 16 mcg/ml.

Human pharmacokinetic studies with cefotetan have demonstrated that its overall mean elimination half-life in plasma is 3.3 hours, which is substantially longer than the elimination half-life of most available cephalosporins.[6]

Early clinical trials involving more than 1300 patients have indicated that cefotetan could be used to treat gynecologic infections and many others caused by gram-positive and gram-negative aerobic and anaerobic pathogens and is well tolerated. The adverse reactions reported in these studies were not life-threatening or serious, and they cannot be considered unusual for a cephalosporin antibiotic.[1]

The evidence from our study suggests that cefotetan may have considerable value as a prophylactic antimicrobial agent used to reduce the incidence of bacterial infections after abdominal or vaginal hysterectomy. In the study, the use of cefotetan was associated with a statistically superior bacteriologic response. More importantly, a single 2 gm intravenous dose of cefotetan compared favorably to a multiple-dose regimen of cefoxitin. Thus this study suggests that use of cefotetan would be associated with large cost savings as well as improved prophylaxis against infection.

The long half-life of cefotetan contributed to the high plasma and tissue levels at approximately 1 hour after administration. This may be particularly important during abdominal hysterectomy, in which tissue contamination (i.e., entry into the vagina) occurs later. Additionally, this regimen is well tolerated by patients. No significant laboratory or clinical side effects resulted from cefotetan administration.

Another technique for resolution of shoulder dystocia

To the Editors:

I read with great interest the article on the Zavanelli maneuver (Sandberg EC. AM J OBSTET GYNECOL 1985;152:479-84.). This unorthodox method of resolving shoulder dystocia seems to be a wise course of action after all other better-known and less-traumatic measures have been taken. Any treatment that saves lives should be tried as a last resort and should be added to one's repertoire of tactics, but I was dismayed to find no mention of one of the most simple, safe, and effective techniques—squatting. This position, well known by midwives and used by those with little recourse to modern technology, has been documented to increase the pelvic capacity by about 30%.[1] This is probably due to the abductive force placed on the ischia (the body weight is partially supported by the adductors that originate from the ischial tuberosities) and facilitated by the pliability of the ligaments at term. A full squat, with feet flat (not on tiptoe) results in a wider pubic angle as the tuberosities are pulled up and apart. This may help free an impacted anterior shoulder.

This position is easily assumed by the mother with the help of a bar for her to grasp.[1] This bar simply fits into the same holes that normally hold the stirrups. It is possible for even a mother with light-to-moderate epidural anesthesia to use the squatting position with the aid of two or more people to support her legs and steady her sacrum.

Although desperate measures such as symphysiotomy or the Zavanelli maneuver may be of great value in a dire emergency, other approaches must be exhausted first. It is unwarranted to resort to such drastic procedures before more physiologic techniques, such as the squatting position, have been tried.

Prostaglandins and endometriosis

To the Editors:

In their recent article, "Peritoneal fluid 6-keto prostaglandin $F_{1\alpha}$ levels in women with endometriosis" (AM J OBSTET GYNECOL 1985;152:901), Mudge et al. present additional evidence that a lack of significant difference exists between women with macroscopic endometriosis and women with no visible disease. Although the data is limited to the luteal phase levels of 6-keto $F_{1\alpha}$, their results are in agreement with other studies performed in the midfollicular phase.[1,2] These studies are in direct contrast to those by Drake et al.[3], who reported significantly elevated levels of 6-keto $F_{1\alpha}$ and thromboxane B_2 in patients with endometriosis as compared to a control group.

At the end of their discussion section, the authors incorrectly state that no single study has measured all of the principal prostaglandins. In November 1983, in this JOURNAL, we reported that peritoneal fluid levels during the proliferative phase of thromboxane B_2, prostaglandin E, prostaglandin F, prostaglandin FM and 6-keto F_1 were not significantly different in women with or without laparoscopically documented endometriosis, irrespective of the clinical stage of disease.[2] In a similar study Dawood et al.[4] also reported peritoneal fluid levels of thromboxane B_2, prostaglandin E_2, prostaglandin $F_{2\alpha}$ and 6-keto $F_{1\alpha}$. This group found significantly elevated concentrations of 6-keto $F_{1\alpha}$ in the group of patients with endometriosis.

At present the issue of peritoneal fluid prostanoid levels in women with endometriosis remains unresolved. Differences in both study protocols and methods of prostanoid analysis make comparison of different studies difficult. It is hoped that in the near future further study will finally resolve this controversy.

Reply

To the Editors:

Dr. Sgarlata correctly indicates that we have overlooked two relevant publications, and we apologize for this omission. We wish to further comment on Sgarlata's observation that Dawood et al. reported elevated peri-

toneal fluid concentrations of 6-keto prostaglandin $F_{1\alpha}$ in women with endometriosis.

Dawood et al. reported a statistically significant increase in the peritoneal fluid concentration of 6-keto prostaglandin $F_{1\alpha}$ in women with endometriosis. However, they also reported that the total peritoneal fluid volumes of women with endometriosis and of normal women are not different, and neither are the total amounts of 6-keto prostaglandin $F_{1\alpha}$. As discussed by Dawood et al. this statistical paradox casts doubt on the pathophysiologic significance of the apparent increase in 6-keto prostaglandin $F_{1\alpha}$ concentration.

Cigarette smoking and endometrial cancer

To the Editors:

Tyler et al. (Endometrial cancer: how does cigarette smoking influence the risk of women under age 55 having this tumor? AM J OBSTET GYNECOL 1985; 151:899-905.) found the risk of endometrial cancer for women under 55 to be reduced approximately 20% among currently smoking women. This was not a statistically significant reduction, but in the discussion of their results the authors failed to point out that their data actually support previous reports of a negative association between cigarette smoking and cancer of the endometrium.[1]

As Hammond and Judd pointed out in the discussion, it is important to note that the Cancer and Steroid Hormone Study assembled an unusually young case series for endometrial cancer. Consequently only the "older" women in this study—those 50 to 54 years old—were in an age group with substantial representation in previous investigations. Among women of this age (more than half of the cases sampled) the Cancer and Steroid Hormone Study data show a particularly strong smoking effect among women who use noncontraceptive estrogens, in agreement with the results published by Weiss et al.[2]

It appears then that cigarette smoking is inversely related to the risk of endometrial cancer, at least in older or postmenopausal women. The mechanisms that might underlie these associations are not clear, but there is evidence that cigarette smoking acts to antagonize estrogen effects in women[1] and in this way may lower the risks of endometrial cancer. Another example of this antiestrogenic effect is the earlier menopause experienced by smokers—on average about 1 to 1.5 years earlier than nonsmokers. This alone could probably not explain a meaningful decrease in endometrial cancer risk, since a menopausal age shift of this magnitude would be associated only with a small change in risk.[1]

A major contribution that Tyler et al. have made is the demonstration that the effect of cigarette smoking may be weaker in younger age groups. Given that premenopausal women differ hormonally from postmenopausal women, it is not surprising to see such a modification by age of the effect of smoking. Another aspect of their work that deserves comment is the finding that ex-smokers seem to revert to the same risk status as never-smokers. This is also true for the relationship between smoking and age at natural menopause and suggests that the hormonal effects of smoking are reversible.[1] Obviously, further research is needed to confirm many of these associations.

Testosterone levels and androgen-producing neoplasms

To the Editors:

The article by Friedman et al. entitled "Serum testosterone concentrations in the evaluation of androgen-producing tumors" (AM J OBSTET GYNECOL 1985; 153:44-9) purports to show that a level of >2 ng/ml of "testosterone" is not predictive of the high likelihood of an androgen-producing neoplasm. We would contend that their report makes quite a different point very well, that is, that there are pitfalls inherent in the use of inadequate assay techniques. Their mean testosterone levels in normal menstruating women are fully twofold higher than the levels of testosterone measured when a chromatographic separation is used rather than direct assay of the ether extract as they described. Thus half of what they have measured consists of a wide variety of cross-reacting materials, any of which could vary markedly because of factors entirely independent of the disease state. In 14 of their 18 subjects most measurements were only mildly in excess of 2 ng/ml. Only by repeat assay of these samples with use of a specific and accurate measurement of testosterone can a meaningful statement be made.

We agree completely with the authors' demonstration of the variability of circulating androgen levels and the suggestion for the measurement on a pool formed by three or four blood samples. We also agree that even with proper assay techniques there will be a rare patient with a testosterone level of >2 ng/ml, generally with hyperthecosis.

The point so well demonstrated by the authors' investigation is the danger inherent in following proposed guidelines based on the use of techniques that were not duplicated during the subsequent clinical care of patients. The temptation is great for clinical labo-

ratories to cut cost and maximize profit by using simpler but less accurate methods. We as clinicians responsible for the care of patients must exert our influence by choosing a quality laboratory. We recognize that in a university center that choice may not be readily available. Perhaps this sort of adverse experience will provide ammunition to overcome the strong forces of cost-containment in the best interests of optimal patient care.

Reply

To the Editors:

We would agree with Dr. Meldrum's point that testosterone levels measured after chromatographic separation are generally lower than those measured directly following ether extraction. This point holds for most steroids including progesterone, which perhaps best exemplifies the trend over the past 15 years toward direct extraction assays and higher peripheral concentrations. It should, however, be acknowledged that most clinical laboratories use either direct extraction assays or newer kits involving direct assays with no extraction.

Our mean normal values were obtained at random times during the menstrual cycle, with normal menstrual cycles being the only criteria for entry. This in part is a bias for higher normal values than would be obtained using the more traditional control of nonhirsute, regularly ovulating women sampled during the early follicular phase. Recognizing the variation in laboratory values, we based our clinical recommendations on multiples of the upper range of normal and included the recommendation of a pooled sample as well as the importance of the clinical presentation.

In defense of the vertical uterine incision

To the Editors:

Dr. Jovanovic (Am J Obstet Gynecol 1985;152:971.) holds Dr. Haesslein and myself responsible for the tendency to deliver the tiny newborn by classical cesarean section. Anyone reading Dr. Hibbard's discussion which followed my 1978 presentation of our paper would realize that our recommendations were considered controversial.[1] Besides, we now attempt to vaginally deliver these tiny babies in cul but still turn to abdominal delivery if any impending difficulty is perceived.[2]

I do not understand Dr. Jovanovic's discussion of the types of uterine incisions. It appears that he is recommending transverse classical (Kehrer) incision for many of these cases, since they often have little or no lower uterine segment. (If the patient has been treated with terbutaline, there may be a reasonable lower segment). However, the reason for abdominal delivery in my view is to achieve an atraumatic delivery of the fetus. In my association with more than 300 of these cases of newborn infants weighing <1000 gm, this can often be achieved only with a vertical uterine incision.[3]

Robert C. Goodlin, M.D.

Reply

To the Editors:

Unfortunately, I have to disagree with Dr. Goodlin one more time, although this time on a different issue. He stated in his letter, "If the patient has been treated with terbutaline, there may be a reasonable lower segment." In other words, Dr. Goodlin claims that terbutaline creates or helps create a lower uterine segment. If terbutaline has any effect on a lower uterine segment, it is completely opposite from that claimed by Dr. Goodlin. The effect of terbutaline on the uterus is manifested by regression of the gap junction and decrease of oxytocin receptor concentration. Such effects on the uterus could only delay formation or growth of lower uterine segment, contrary to Dr. Goodlin's claim.

Going back to my paper, "Incisions of the pregnant uterus and delivery of low-birth weight infants," I would like to outline that I never recommended or even mentioned classical transverse (Kehrer) incision. I recommended a transverse upward concave incision over a partially developed lower uterine segment. This incision gives us unquestionably larger entrance to the uterus than the so-called "finger tear" of the lower uterine segment, and we do not have to overcome uterine spasm as in the case of vertical midline uterine incisions to achieve an atraumatic delivery of the fetus.

In addition to that, low transverse upward concave incisions made on even partially developed lower uterine segments appear to be durable, because of the fol-

lowing reasons, as stated in my paper: (1) "The proportion of smooth muscle in the myometrium decreases from the fundus to the cervix." (2) "Connective tissue of the uterus increases proportionally toward the cervix." (3) "The uterine structure is such that weaker points are in a longitudinal direction and that is why the most common type of tear in the unscarred uterus is a longitudinal one." (4) "The strong uterine structure is in the transverse direction of the lower part of the uterus so that even a dehiscent transverse scar sustains labor, and sometimes delivery, well."

I have opened the uterus transversely and concave upward over the partially formed lower uterine segment many times, as have many other obstetricians, but I have never observed and it has never been reported that this incision is less durable than the finger tear incision over completely formed and enormous lower uterine segment.

Additional comment on combination conization

To the Editors:

It is with some amusement that I read the letters regarding the so-called combination conization (AM J OBSTET GYNECOL 1985;153:343-5).

I note that Drs. Grant, Rouse, and Minielly as well as Wright feel a bit remiss in that Dr. Wright was not even credited for this technique. It is odd that the Wright and Rubinstein letters have the same reference. This must, of course, be by accident.

In reviewing some of my own literature, I note that the so-called cylinder cone that Dr. Wright takes credit for was mentioned in some of our early articles and books in the early 1970s, but we did not call it a "cylinder cone." We called it a long narrow cone. We also described the so-called ring biopsy, which is really nothing new.

In 1971 we combined the ring biopsy and the cylinder cone. Unfortunately, we did not have the modern method of laser vaporization. We were forced to use the old scalpel and cautery.

I did not think it was worthwhile to publish this particular technique but talked about it at great length during many colposcopy courses. Also several of our Canadian Fellows became acquainted with the techniques before their return to Canada after spending some time at the Los Angeles County Southern California Medical Center in colposcopy and gynecologic oncology. We made slides of the technique in 1972 before most physicians even looked through a colposcope, much less used a laser.

Again, it is mind-boggling to note the obvious paranoia over such a simple process. There is no question that history repeats itself. I am sure others have used the "combination cone" without credit.

I am afraid that the credit for this technique will have to stay in the good old U.S.A., as suggested by Dorsey and Baggish.

Maternal and fetal surveillance for older pregnant women

To the Editors:

We read with great interest the recent article by Kirz et al. (Advanced maternal age: the mature gravida. AM J OBSTET GYNECOL 1985;152:7-12.). We wholeheartedly agree that all women, regardless of age, deserve to be treated with the utmost respect, sensitivity and compassion. We also agree that pejorative terms such as "elderly gravida" should be eliminated from the obstetric literature. We are not quite sure that "mature gravida" is the best term to use as a substitute. Unfortunately, maturity does not always correlate with increasing age in either women or men.

We do not agree with the authors' interpretation of the data presented in the article, however. In careful detail they have demonstrated that women above the age of 35 years did indeed have a higher incidence of maternal and perinatal complications. Such complications included a higher incidence of hypertension, diabetes, cesarean delivery, operative vaginal delivery, breech presentation, macrosomia, congenital anomalies, and late decelerations in labor. Many of these differences in pregnancy outcome still were apparent when women with preexisting medical or obstetric complications were excluded from the study and control groups—a questionable exclusion since it is precisely the increased incidence of certain of these medical diseases in the "older" women that places them at increased risk for complications in the first place.

There is no question that maternal and fetal outcome in this series was very good. We think this is due to the excellent obstetric care provided by the authors, not to the fact that the study patients were not at increased risk. The study of Kirz et al. actually has reaffirmed our commitment to provide intensive maternal and fetal surveillance for patients in their mid to late thirties.

Reply

To the Editors:

I am pleased that Schipul et al. were interested enough to read and comment on my article on pregnancy and advanced maternal age. I will address first what I think is the most important issue they raise: the question of analyzing a category of "healthy" older

gravid women. I certainly agree that as people age there is an increase in systemic diseases such as hypertension and diabetes. If a pregnant woman has these problems, then she should be considered to be at high risk. Of course, that is true whether she is 25 or 35 years old. These diseases alone put the patient in the high-risk category without consideration of age. More older women have these problems, therefore more older women are going to be at high risk. In that sense older women as a category are at higher risk than younger women. What about the women 35 years and older who do not have these medical problems? Are they at high risk because of age alone? Many of the previous studies have not tried to isolate age as a risk factor. The few that have do not find that age alone is a risk factor for significant perinatal problems.[1, 2] In my study the healthy gravid women (both parous and nulliparous) did not demonstrate an increase in the development of pregnancy complications. These include preterm labor, postdatism, preterm rupture of membranes, meconium, third-trimester bleeding, hydramnios, and problems with weight gain or urinary tract infections. In fact, there was an increase in preterm labor among the younger control group as compared to the older group. In regard to neonatal outcome the healthy nulliparous pregnant women did have more macrosomic babies, low 1-minute Apgar scores, and congenital anomalies. There was, however, no differences in 5-minute Apgar scores, perinatal deaths, or admissions to the neonatal intensive care unit.

The increase in congenital anomalies was probably due to the increase in chromosomal alterations with advancing age. With the healthy parous gravid patients there was no difference in any of the neonatal outcome parameters with regard to age.

In commenting about delivery modalities it is indeed true that the older group did have more operative deliveries. It is difficult to judge how many of these interventions were based on the concept of "high risk pregnancy" or "precious baby." It is possible that an obstetrician may have been more likely to expedite the delivery based on concern that this was a higher-risk pregnancy. Also, the increase in epidural anesthesia may have played a role in the use of vacuums and low forceps.

The nulliparous and parous "all" categories did demonstrate more problems with systemic diseases of aging. This was not surprising. Interestingly, preterm labor was more prevalent in the younger group with subsequent increase in low birth weight and neonatal admissions. As you pointed out in your letter, the "all parous gravidas" category did have more late decelerations, but there was no increase in meconium, low Apgar scores, or neonatal admissions for these same babies.

I suspect that a significant part of the good maternal and fetal outcome in this series was indeed related to the quality of the care provided in this tertiary care center. I, too, encourage obstetricians to maintain intensive maternal and fetal surveillance for their patients. Perhaps the message is that with our current standards of care for all of our patients there may be no significant increased risk in pregnancy for the women in their mid to late thirties.

As a final point, it was interesting to note that you object to my suggestion that we apply the adjective "mature" in describing these older gravid women. The word mature as defined in Webster's *Unabridged Dictionary*[3] has several possible definitions: (1) Completely developed or grown; fully ripe. (2) Highly developed or advanced in intellect, moral qualities, outlook, etc.; mature thinker. (3) Fully or thoroughly developed, perfected, detailed, etc.; a mature scheme. (4) Having reached its time limit; due and payable; a mature bond.

Clearly my intent in using the word mature is as in definition 1 not as in definition 2. I suspect the difference in definitions is where our disagreement lies. You stated, "unfortunately, maturity does not always correlate with increased age in either women or men." I, of course, cannot attest to development or advancement in intellect with age.

I do think that mature as referred to in my article as "having completed natural growth and development, having attained a final or desired state, condition of full development," is a preferable term to use rather than elderly, premenopausal, geriatric, etc. I am quite open to other suggestions if you have an alternative term in mind. Until then I continue to propose that we do not use terms such as elderly primigravida but instead consider a more gentle designation such as mature gravida.

Another view of controversy about Rh prophylaxis

To the Editors:

I would like to comment on some recent correspondence (AM J OBSTET GYNECOL 1985;153:112-3). I refer to the letter, "Controversies in Rh prophylaxis," and the response by Dr. Bowman.

As a coauthor of an article on Rh isoimmunization,[1] I have an opinion to express which may or may not have some validity. I am disappointed to see in this "argument" a possible development that sounds like a

personal vendetta, with Dr. Hensleigh appearing to support an academic stance and Dr. Bowman appearing to support a clinical stance. In the first instance, one should always remember that a numerical or statistical significance does not always correspond with clinical relevance, and one could apply that to the arguments made by both of them. It seems that one can also see in this "argument" some similar analogies to the controversy regarding the safety of ultrasound. In one camp you have reputable authorities cautioning against the wider use of "routine" obstetric ultrasound studies on the grounds that the safety of ultrasound has not been proved and, on the other side, equally reputable authorities making statements that they perform routine obstetric ultrasound studies on the assumption that in the absence of any demonstrated harm, the "benefits outweight the undetermined risks."

Surely there is not one answer in Dr. Bowman's arguments that appears to have the flavor of a campaign. The additional information provided will be useful in decision making, but one must realize that in medical practice in the United States omnipotence is not well received and decisions involve (or should involve) more than just the authoritative voice of one obstetrician; therefore one could only commend Dr. Hensleigh for having developed a patient counseling tool, "Information for Rh-negative patients." In this way, a primary care obstetrician in conjunction with the patient/couple may be able to arrive at her/their own informed decision on this controversial subject.

One last issue to mention is that both arguments are defensible and it is important in the current medical legal climate in which obstetrics is practiced in the United States that, in the event that a defense is necessary (and the attacks come for either using or failing to use RhoGAM before birth), it is essential for clinicians to know they have potential defenders of their clinical practice when there continues to be such controversy.

A rapid method of culturing bloody amniotic fluid for chromosome analysis

To the Editors:

The amniotic fluids are routinely cultured for prenatal diagnosis of genetic disorders. At least 5% to 10% of the specimens contain maternal or fetal blood cells. The culturing of such samples is not only difficult but frequently results in unsuccessful growth. Also, the cultures initiated with bloody samples usually take longer time with the standard protocol. We made a few modifications that provide results within 10 to 15 days and wish to share our experiences with other cytogenetic laboratories.

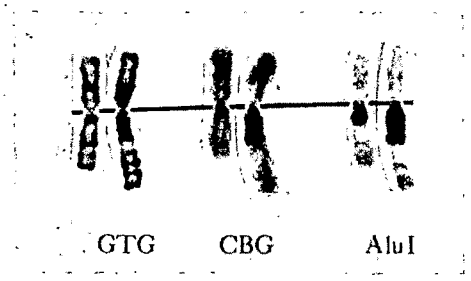

Fig. 1. Chromosome 1 from a bloody amniotic fluid with male karyotype. Results were obtained in 9 days. One of the chromosomes had an enlarged secondary constriction region (h), which was immediately confirmed by Alu I technique. Presence of this chromosome was noted in the mother.

Our culturing medium consists of the following: 100 ml of RPMI 1640 (Gibco No. 320-1875), 1.2 ml of penicillin-streptomycin (Gibco No. 600-5140), 1.2 ml of L-glutamine (Gibco No. 320-5039), and 25 ml of fetal bovine serum (Gibco No. 240-6290).

It should be emphasized that the media contain 25 ml of fetal bovine serum instead of 20 ml under normal conditions. Primary cultures should be left undisturbed in flasks for an additional 2 days, that is, up to 7 days instead of 5 days. In normal conditions the medium is changed twice a week whereas these cultures require changing at least three times a week. The cultures are usually ready to be trypsinized and the cells dispersed after the second change of medium. The reconstituted culture medium should not be more than 4 days old. The temperature of media should be 37° C before use. Although these are very minor variables, in our experience they have proved to be very important.

Another frequent problem is that certain individuals have homologues with variable lengths, whether they are polymorphic forms or chromosomal abnormalities.[1] Such incidences are more often found in chromosomes 1, 9, and 16. In these cases, the C-banding technique is being routinely used, which requires aging of the slides and consequent delay in results. Currently we have found an alternative whereby these polymorphic regions can be examined in a few hours by treating the chromosomes with restriction endonuclease Alu I (Fig. 1). We have described the elaborate method for Alu I, which can be obtained upon request.[2]

Sterilization failures

To the Editors:

Having a considerable interest in tubal sterilization failures, I relished the opportunity to read Dr. Soderstrom's reported extensive clinical experience (Soderstrom RM. Sterilization failures and their causes. AM J OBSTET GYNECOL 1985;152:395.). I must, however, take exception to the statement made that referred to my previous publication.[1] The purpose of that study was to analyze the healing process subsequent to sterilization and consequently the cause for failures. I found no evidence that so-called "recanalization" or "endosalpingiosis" played any role. Rather, an expected normal tissue response was encountered. In the article, I also described the mechanism for the failure of the Kroener procedures, and it has nothing to do with the fimbria ovarica. The problems with the bipolar failures were recently addressed quite extensively in a series of letters to the editor in *Fertility and Sterility*.[2] The question of procedural errors was rightly pointed out. In cases that I have had the opportunity to review, some of which were impending medical-legal problems, three features stand out: (1) incomplete operative notes as far as description of equipment used, site or sites of coagulation, and the end point used for the coagulation; (2) improper handling of the excised tubal segment so that histologic reconstruction is difficult if not impossible; and (3) a failure on the part of the pathologist to recognize the coagulative effects and consequently an inappropriate final diagnosis or comment. These latter problems may lead to medical-legal action.

I wholeheartedly agree with Dr. Soderstrom's closing statement that in patients with prior sterilization failures, the tubal segments in question should be removed and studied; however, it is imperative that the segments be appropriately handled and correct histolopathologic diagnoses be made.

Reply

To the Editors:

Dr. Stock is quite correct in his criticism of my reference to his article when I discussed endosalpingosis as an iatrogenic cause of sterilization failure. I meant to reference McCausland's article [McCausland A. Endosalpingosis ("endosalpingoblastosis") following laparoscopic tubal coagulation as an etiologic factor of ectopic pregnancy. AM J OBSTET GYNECOL 1982; 143:12]. My apologies to Dr. Stock and of course to Dr. McCausland.

My pathologists disagree with Dr. Stock since endosalpingosis nodosum has been present in a few of my sterilizaton failures, particularly at the proximal end of a fistula tract that formed after unipolar sterilization. Perhaps because Dr. Stock experienced electrical method failures with only two patients, a larger series might unroof a case of endosalpingosis.

I did not refer to Dr. Stock when I discussed the presence of fimbriae ovarica in all nine patients with failure of fimbriectomy sterilization. It was quite clear to me that the presence of a healthy fimbria ovarica would enhance ovum pickup and transfer to the patent tubal stump.

The three features he referred to when discussing his medicolegal experience are the same features that have been present during my medicolegal experience.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Perinatology Press

RESPIRATORY CONTROL AND LUNG DEVELOPMENT IN THE FETUS AND NEWBORN

B.M. Johnston & P.D. Gluckman, Eds.
20 Contributors.

Clinical and research efforts have blended together over the last few years to enhance our knowledge of the physiology and pathophysiology of respiration and lung development in the fetus and newborn. The contributors to this volume have made fundamental contributions to our knowledge of the biochemistry, endocrinology and physiology of fetal lung development.

Modern diagnostic and therapeutic regimes are firmly based on animal studies and carefully controlled clinical trials relating to surfactant production, lung development and the development of the sensory and neural elements that control fetal and neonatal breathing. 428 pages. 1986 $50.

INTRAUTERINE GROWTH

P.W. Nathanielsz, Ed. 14 Contributors.

This fourth volume in the series, Animal Models in Fetal Medicine considers problems that are of fundamental importance in obstetrics and pediatrics. The book details and critically assesses investigation of regulation of fetal growth. It deals with the function of the fetal kidney and liver, and the measurement of blood and other body fluid volumes. Other contributions deal with placental transfer, substrate metabolism and fetal surgery in conditions of growth retardation. 216 pages. 1985. $45.

PARTURITION

P.W. Nathanielsz, Ed. 18 Contributors.

Parturition involves several physiological and biochemical systems. This volume considers the peptides of the hypothalamus and pituitary that are responsible for regulation of the fetal adrenal. Human, nonhuman primate, sheep and small animal experiments are carefully analyzed. In vitro, electron microscopy and computerized whole animal techniques are described and evaluated. The latest methods of studying fetal metabolism with nuclear magnetic resonance spectroscopy are described in detail. Together, the chapters describe how ideas on maternal and fetal function during normal and abnormal labor have been formulated. 320 pages. 1986. $50.

FETAL PHYSIOLOGY AND MEDICINE

R.W. Beard & P.W. Nathanielsz, Eds.
43 Contributors.

The second edition of this outstanding text covers all the important areas of fetal development. Contributors include Drs. J.C. Hobbins, J.D. Wilson, R.D.G. Milner, A. Jobe, P.D. Gluckman, G.C. Liggins, F.C. Battaglia and many other international leaders in perinatology. This book is essential reading for the obstetrician or neonatologist who wishes to keep up-to-date.

The first edition of this book was described as "... outstandingly successful...there can be few clearer or more comprehensive accounts of the physiological basis of modern obstetrics."... *British Medical Journal.* 823 pages. 1984. $70.

The Royal College of Obstetricians and Gynaecologists Study Groups

---

PRETERM LABOUR AND ITS CONSEQUENCES

R.W. Beard & F. Sharp, Eds. 26 Contributors.

Speakers from the major research and clinical centers throughout the world joined together to consider the many factors such as incidence and distribution, prevention, complications and management that make up the complex condition of Preterm Labor. Epidemiology, perinatal physiology and pathology are discussed in depth and a better understanding of the condition emerges. Fetal and neonatal pulmonary and brain function are discussed. The roles of psychological stress, infection and fetal abnormality and other causative factors are considered as well as the most up-to-date methods of management. 403 pages. 1985. $55.

IN VITRO FERTILIZATION AND DONOR INSEMINATION

W. Thompson, D.N. Joyce & J.R. Newton, Eds. 29 Contributors.

This volume contains contributions from clinicians such as Drs Edwards, Steptoe and Jones who have pioneered many of the procedures described. In addition, the basic sciences underlying the practice of in vitro fertilization are discussed in detail. The experiences in different countries throughout the world and the legal aspects are also considered in depth. Various chapters cover egg collection, embryo culture methods, semen evaluation and pregnancy outcome. 346 pages. 1985. $55.

LITIGATION AND OBSTETRICS AND GYNAECOLOGY

G.V.P. Chamberlain, Ed. 23 Contributors.

The medico-legal aspects of obstetrics and gynecology are a common cause for interest and concern for the practitioner and the legal profession. Rapid and complex changes have taken place in the field of malpractice in recent years. In this volume, the major areas of obstetrics and gynecology, such as anesthesia, abortion, contraception, sterilization, fetal hypoxia, operative deliveries and home delivery are discussed. This volume is essential reading for all practitioners in the field. The time and money invested in reading this book could well avoid malpractice problems. 350 pages. 1985. $55.

GYNAECOLOGICAL LASER SURGERY

F. Sharp & J.A. Jordan, Eds. 30 Contributors.

For this Study Group the Royal College assembled the world's leading gynecological laser surgeons, laser physicists and other specialists in the field. Areas covered include basic laser physics, laser delivery systems and safety; and laser treatment of lower genital tract, intra-abdominal and endoscopic applications in gynecology. Training of gynecologists in laser techniques is discussed and guidelines outlined. This volume will be of value to gynecologists already engaged in laser surgery, those contemplating these techniques, and importantly, gynecologists wishing to learn what laser surgery can offer their patients. 322 pages. 1986. $55.

EARLY PREGNANCY FACTORS

F. Ellendorff & E. Koch, Eds. 29 Contributors.

This volume is a comprehensive review of current knowledge on the major problems of early pregnancy. It discusses the physiological role of steroids, prostaglandins and proteins in maternal recognition of pregnancy. Consideration is given to the interaction of embryo and mother at the endocrine, immunological and cardiovascular levels. This volume is essential reading for scientists and clinicians involved with in vitro fertilization, embryo transfer and all other aspects of the physiology and pathophysiology of early pregnancy. 272 pages. 1985. $35.

PERINATAL ENDOCRINOLOGY

E. Albrecht & G. Pepe, Eds. 17 Contributors.

A comprehensive review of fetal, neonatal and placental endocrinology. The authors include P.D. Gluckman, J. Rose, D.A. Fisher, C. Rosenfeld, C. Cheung, M. Seron-Ferre, J.D. Winter, E. Simpson, A. Klopper, E. Albrecht, G. Pepe, J.R.G. Challis, P.W. Nathanielsz, M. Soloff, and others who have made fundamental contributions to the rapidly expanding body of knowledge in this area. 315 pages. 1985. $40.

FETAL NEURO-ENDOCRINOLOGY

F. Ellendorff, P.D. Gluckman & N. Parvizi, Eds. 33 Contributors.

This was the first international meeting devoted to this developing field of perinatal research and this volume is a comprehensive compilation of reviews and papers by key workers studying the development of the neuroendocrine system. Topics covered include: neurogenesis in the mammalian brain, the role of the neuropeptides and neurohormones in neural development, the ontogenesis of neurotransmitter systems, fetal hypothalamic transplantation, fetal hypothalamic cultures, and many other important areas in relation to the significant neuroendocrine axes. 285 pages. 1985. $35.

The University of Louisville is an equal opportunity/affirmative action employer.

Associate Professor/Professor Maternal Fetal Medicine

The Department of Obstetrics & Gynecology of the University of Texas Health Science Center at Dallas is recruiting for a full-time faculty position for the Division of Maternal Fetal Medicine at the Associate Professor/Professor Level. Requisites include that the applicant be board certified in Maternal-Fetal Medicine, Texas licensure, and have suitable academic credentials that include proven performance in laboratory and clinical research. The position includes a heavy clinical schedule with supervision of fellows, residents, and medical students. Interested applicants should send their curriculum vitae to:

F. Gary Cunningham, M.D.
Department of Obstetrics & Gynecology
University of Texas Health Science Center
at Dallas/Southwestern Medical School
5323 Harry Hines Boulevard
Dallas, TX 75235-9032

An Affirmative Action/Equal Opportunity Employer

PERINATOLOGIST

Texas Tech University, Odessa Regional Academic Health Center join IV academic department in West Texas. Be a part of our four campus Ob/Gyn system. Competitive salary and excellent fringe benefits program available to ABOG eligible or certified in Perinatology. Send inquiry and CV for the above to:

Robert Carter, M.D., FACOG
Professor and Association Chairman of Ob/Gyn
Medical Center Hospital
P.O. Drawer 7239
Odessa, Tx. 79760
or call (915) 335-5200

Texas Tech University Health Sciences Center is an equal employment opportunity and affirmative action employer.

FULL TIME FACULTY POSITION IN THE DIVISION OF GYNECOLOGIC ONCOLOGY

Dept. of Obstetrics and Gynecology, Jefferson Medical College of Thomas Jefferson University. Board certified or board eligible subspecialists in gynecologic oncology to join this division in its clinical, teaching and interdisciplinary research activities. Applicants please submit CV to:

James H. Lee, Jr., MD
Professor and Chairman
Dept. of Obstetrics & Gynecology
Jefferson Medical College
Room 310 College Building
1025 Walnut St.
Philadelphia, PA 19107

EOE

MATERNAL-FETAL MEDICINE FACULTY POSITION

The Division of Maternal-Fetal Medicine of the Department of Obstetrics and Gynecology at the University of Florida College of Medicine in Gainesville, Florida has an opening for a full-time faculty position at the Assistant to Professor rank.

Board eligibility or certification in Maternal-Fetal Medicine is required and training or experience in obstetric ultrasound is desirable.

Salary and rank commensurate with training and experience. Application Deadline: April 30, 1986. Anticipated Starting Date: 7/1/86.

Send curriculum vitae to:

Amelia C. Cruz, M.D.
Department of Obstetrics and Gynecology
J-294, JHMHSC
University of Florida College of Medicine
Gainesville, Florida 32610

"An Equal Employment Opportunity/Affirmative Action Employer"

Gynecologic Oncologist

Texas Tech University, Odessa Regional Academic Health Center join IV academic department in West Texas. Be a part of our four campus Ob/Gyn system. Competitive salary and excellent fringe benefits program available to ABOG eligible or certified in gyn oncology. Candidates should be interested in clinical oncology, teaching, and regionalization. Send inquiry and CV for the above to:

Robert Carter, M.D. FACOG
Professor and Association Chairman of Ob/Gyn
Medical Center Hospital
P.O. Drawer 7239
Odessa, Tx. 79760
or call (915) 335-5200

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $6.95 each, postpaid (3 for $20.00, 6 for $36.00). Add $2.50 postage per case for orders outside U. S. Prepayment must be in U. S. funds only. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

Jesse Jones Box Corporation (est. 1843)
P. O. Box 5120
Philadelphia, Pa. 19141

Please send me, postpaid ___ library cases for AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY at $6.95 each (3/$20.00, 6/$36.00.)

☐ **NEW SIZE (8¼" × 11") 3 cases/year**
☐ **OLD SIZE (7¼" × 10½") copies prior to 1975 (2 cases/year)**

ORTHO-NOVUM 1/7/7 Tablets

TRADEMARK

(norethindrone/ethinyl estradiol)

Unique, week-by-week design

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert).**

DRUG INTERACTIONS: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

A choice that's right

for both of you.

- 29% lower progestin dose than 1/35.[1]
- Full-cycle breakthrough bleeding control equal to 1/35.[1]
- Unique "low-higher-low" phasing for extra mid-cycle protection.
- Norethindrone-based for low metabolic impact.[2,3]
- Supplied in the patient-preferred Wallette™ pill dispenser.[4]

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

1. 1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. BTB comparisons are based on the first three cycles of use. Data available from Syntex Laboratories, Inc.
2. Wynn V, Niththyananthan R: The effect of progestins in combined oral contraceptives on serum lipids with special reference to high-density lipoproteins. *Am J Obstet Gynecol* 142:766-772, 1982.
3. Wynn V: Effect of duration of low-dose oral contraceptive administration on carbohydrate metabolism. *Am J Obstet Gynecol* 142:739-746, 1982.
4. In an independent survey the Wallette™ pill dispenser was preferred to the Ortho Dialpak by 7 out of 10 prospective OC patients. Data available from Syntex Laboratories, Inc.

TRI-NORINYL® TABLETS

(NORETHINDRONE AND ETHINYL ESTRADIOL)

Because your common goal is confidence.

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)
BREVICON® 21-Day Tablets (norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
BREVICON® 28-Day Tablets (21 norethindrone 0.5 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 35 21-Day Tablets (norethindrone 1 mg with ethinyl estradiol 0.035 mg)
NORINYL® 1 + 35 28-Day Tablets (21 norethindrone 1 mg with ethinyl estradiol 0.035 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 50 21-Day Tablets (norethindrone 1 mg with mestranol 0.05 mg)
NORINYL® 1 + 50 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.05 mg tablets followed by 7 inert tablets)
NORINYL® 1 + 80 21-Day Tablets (norethindrone 1 mg with mestranol 0.08 mg)
NORINYL® 1 + 80 28-Day Tablets (21 norethindrone 1 mg with mestranol 0.08 mg tablets followed by 7 inert tablets)
NORINYL® 2 mg Tablets (norethindrone 2 mg with mestranol 0.1 mg)
NOR-Q.D.® (norethindrone) Tablets 0.35 mg

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.
MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to non-smoking users, and a 10-12-fold increased risk compared to nonsmoking non-users. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences,* or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned.
Precautions *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings.
Adverse Reactions An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms, (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

Betadine
Vaginal Microbicides
by night.

Now there are two overnight Betadine Vaginal Microbicides for relief of vaginitis symptoms: Betadine Antiseptic Gel and *new* Betadine Vaginal Suppositories. Both offer continuous contact with the vaginal mucosa for continuous relief of pruritus, burning, erythema and odor. The gel may also be used for external irritation and pre-op prepping; the suppositories deliver a measured dose of proven effective povidone-iodine every time.

One tablet is the total treatment

Mycelex®-G 500 mg
(clotrimazole) Vaginal Tablet

INDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended. The diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis, *Trichomonas* and *Gardnerella (Haemophilus) vaginalis*, should be ruled out by appropriate laboratory methods.

CONTRAINDICATIONS: Mycelex®-G 500 mg Vaginal Tablets are contraindicated in women who have shown hypersensitivity to any components of the preparation.

WARNINGS: None.

PRECAUTIONS: If there is a lack of response to Mycelex®-G 500 mg Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.

CARCINOGENESIS: No long term studies in animals have been performed to evaluate the carcinogenic potential of Mycelex®-G 500 mg Vaginal Tablets intravaginally. A long term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.

USAGE IN PREGNANCY: PREGNANCY CATEGORY B: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.

In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy.

Studies in pregnant rats given repeated intravaginal doses up to 100 mg/kg/day have revealed no evidence of harm to the fetus due to clotrimazole.

Repeated high oral doses of clotrimazole in rats and mice ranging from 50 to 120 mg/kg resulted in embryotoxicity (possibly secondary to maternal toxicity), impairment of mating, decreased litter size and number of viable young and decreased pup survival to weaning. However, clotrimazole was not teratogenic in mice, rabbits and rats at oral doses up to 200, 180 and 100 mg/kg, respectively. Oral absorption in the rat amounts to approximately 90% of the administered dose.

Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.

ADVERSE REACTIONS: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.

Eighteen (1.6%) of the 1116 patients treated with Mycelex®-G in other formulations in double-blind studies reported complaints during therapy that were possibly drug-related. Mild burning occurred in six patients while other complaints such as skin rash, itching, vulval irritation, lower abdominal cramps and bloating, slight cramping, slight urinary frequency, and burning or irritation in the sexual partner, occurred rarely.

OVERDOSAGE: No data available.

DRUG ABUSE AND DEPENDENCE: Drug abuse and dependence with Mycelex®-G 500 mg Vaginal Tablets has not been reported.

DOSAGE AND ADMINISTRATION: The recommended dose is one tablet inserted intravaginally one time only, preferably at bedtime. In the event of treatment failure, that is, persistence of signs and symptoms of vaginitis after five days, other pathogens commonly responsible for vaginitis should be ruled out before instituting another course of antimycotic therapy.

HOW SUPPLIED: Mycelex®-G 500 mg Vaginal Tablets are white, bullet shaped, uncoated tablets, coded with Miles on one side and 097 on the other, supplied as a single 500 mg tablet with plastic applicator and patient instructions.

The simplest way to

There are still many who perform a CBC or hematocrit as soon as anemia is suspected, even though it is in fact the Hb value that defines anemia.

There is a simpler way.

Determine the Hb level directly. If it lies below the reference standard, it is reasonable to suspect anemia. A detailed patient history will then disclose whether it is caused by a deficiency in iron or loss of blood.

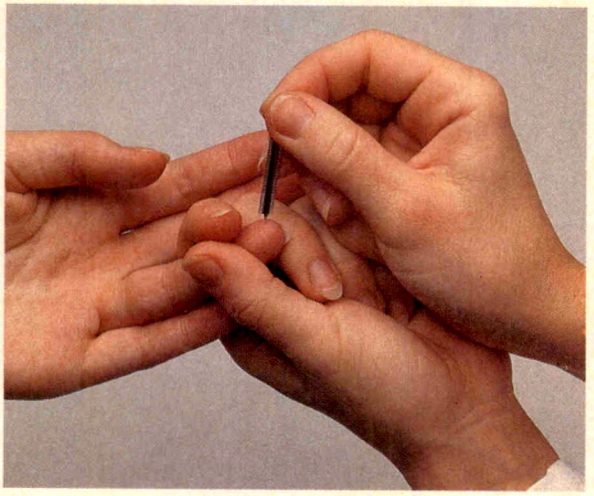
But...

The Hb level varies from person to person. It thus makes sense to monitor each individual patient's Hb level routinely to identify early signs of anemia.

For this you would require a test procedure that could be performed in-office with minimal risk of functional and human error.

This is where the HemoCue Hb test comes in.

The HemoCue system is designed to eliminate possible sources of error. It is so simple to handle that anyone can perform accurate Hb determinations in 60 seconds or less.



Going the long way around through CBC, or via hematocrit, you can get there quicker and safer with HemoCue. And have the test result before the patient leaves your office!

For more information on this new, economical test, call 800-323-1674 (CA 714-859-7779).

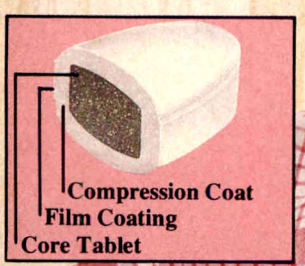
Natalins® Rx

Multivitamin and Multimineral Supplement with 1 mg Folic Acid

The Only Prenatal Vitamin with No Artificial Color or Flavor from Synthetic Sources

The Recipe for Prenatal Good Health



Good things are made from the finest ingredients. And the ingredients for maintaining good prenatal health make NATALINS Rx a standout . . . inside and out.

NATALINS Rx is the first and only prescription vitamin and mineral supplement with "natural" color and flavor. It contains all the mandatory and optional vitamins and minerals, plus copper and zinc, both important in the metabolic process.

Unique NATALINS Rx Construction Aids Compliance and Maintenance of Good Health

An elliptical tablet shape and a cellulosic film coating that becomes slippery when wet allows for easier, more comfortable swallowing—aiding patient compliance. Beneath the special coating, a central "core tablet" stores iron for delayed release, reducing the risk of stomach upset.

NATALINS Rx . . . the "Natural" Choice for Prenatal Good Health.

NATALINS® Rx

Ingredients	Natalins Rx	
VITAMINS	**Units**	**% RDA**
Vitamin A, IU	8000	100
Vitamin D, IU	400	100
Vitamin E, IU	30	100

Zinc, mg	15	100
Artificial color	none	
Artificial flavor	none	

Natalins Rx is a multivitamin, multimineral supplement for pregnant or lactating women. Daily dose: 1 tablet or as prescribed.
Contraindications: Natalins Rx should not be prescribed in patients with hemochromatosis or patients with Wilson's disease.
Caution: Pernicious anemia should be excluded before using this product. In patients with kidney stones, the calcium content of Natalins Rx tablets should be considered before prescribing.
Supplied: Bottles of 100 and 1,000.

Outstanding mixed aerobic/anaerobic coverage

Cefizox® IM IV

brand of sterile

ceftizoxime sodium

Injection: 1 and 2 gram vials

- **B.I.D. Dosing† for All but Life-Threatening Infections**
- **Clinical Cure Unsurpassed By Clindamycin/Tobramycin[1]**

  A recent, prospective, randomized, comparative trial demonstrated that 'Cefizox' was equal to clindamycin/tobramycin in the treatment of intra-abdominal infections.
- **Better Gram-negative and *Bacteroides* Coverage Than Mefoxin® (cefoxitin)‡**

Aerobic Organisms[2] (number of strains)	CEFIZOX® (ceftizoxime) MIC_{90}	MEFOXIN® (cefoxitin) MIC_{90}
Gram-Negative	mcg./ml.	mcg./ml.
Escherichia coli (40)	0.04	6.3
Klebsiella pneumoniae (32)	0.05	25
Enterobacter aerogenes (16)	0.12	>400
Enterobacter cloacae (16)	0.8	400
Proteus sp. (indole positive) (26)	6.3	12.5
Citrobacter sp. (32)	0.2	400
Gram-Positive	mcg./ml.	mcg./ml.
Staphylococcus aureus (16)	3.1	3.1

Bacteroides species[3] (number of strains)	CEFIZOX® (ceftizoxime) MIC_{90}	MEFOXIN® (cefoxitin) MIC_{90}
B. fragilis (55)	8 mcg./ml.	16 mcg./ml.
B. ovatus (17)	16 mcg./ml.	64 mcg./ml.
B. thetaiotaomicron (13)	64 mcg./ml.	32 mcg./ml.
B. distasonis (12)	8 mcg./ml.	32 mcg./ml.
B. vulgatus (3)	8 mcg./ml.	16 mcg./ml.

* Due to susceptible strains of indicated organisms.

† Dosage in renally compromised patients may require adjustment. Please see complete prescribing information.

‡ *In vitro* activity does not necessarily imply *in vivo* effectiveness.

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae*. 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

***Pseudomembranous colitis* has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who developed diarrhea in association with antibiotic use.** Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of *Clostridia*. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro*. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Careful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established.

Nursing Mothers: 'Cefizox' is excreted in human milk in low concentrations. Caution should be exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not been established. In children six months of age and older, treatment with 'Cefizox' has been associated with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phosphokinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, but less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGOT, SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elevations of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*—Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomiting have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams of ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxime.

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams of ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufactured for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

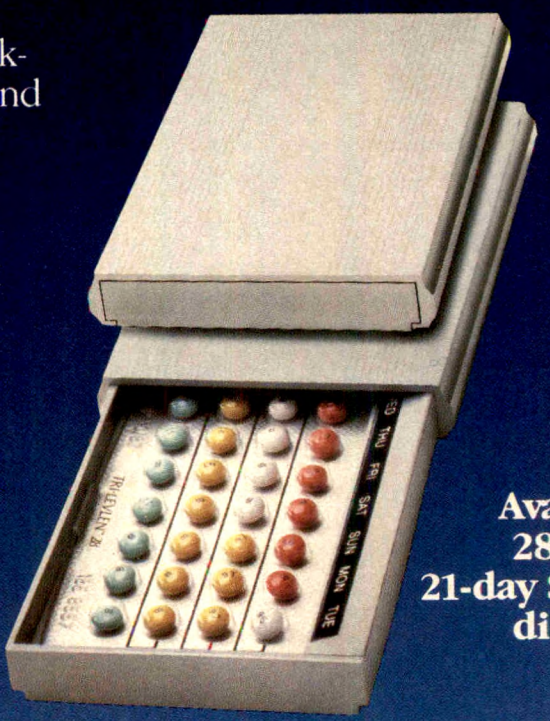
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These d represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

A formulation with the lowest total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Low incidence of breakthrough bleeding



A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

Minimal impact on the following metabolic and hemodynamic parameters*

Lipids,[2,3] carbohydrate metabolism[2,3] and blood pressure[1] were not significantly affected in certain specific studies.

A formulation with the confidence of 170 million cycles of experience worldwide

Available in 28-day and 21-day Slidecase™ dispensers

TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if

applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the U.S. National Library of Medicine in *Cumulated Index Medicus*. Journal titles should also conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper. For black and white illustrations, submit three sets of 5 by 7 inch (8 by 10 inch maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

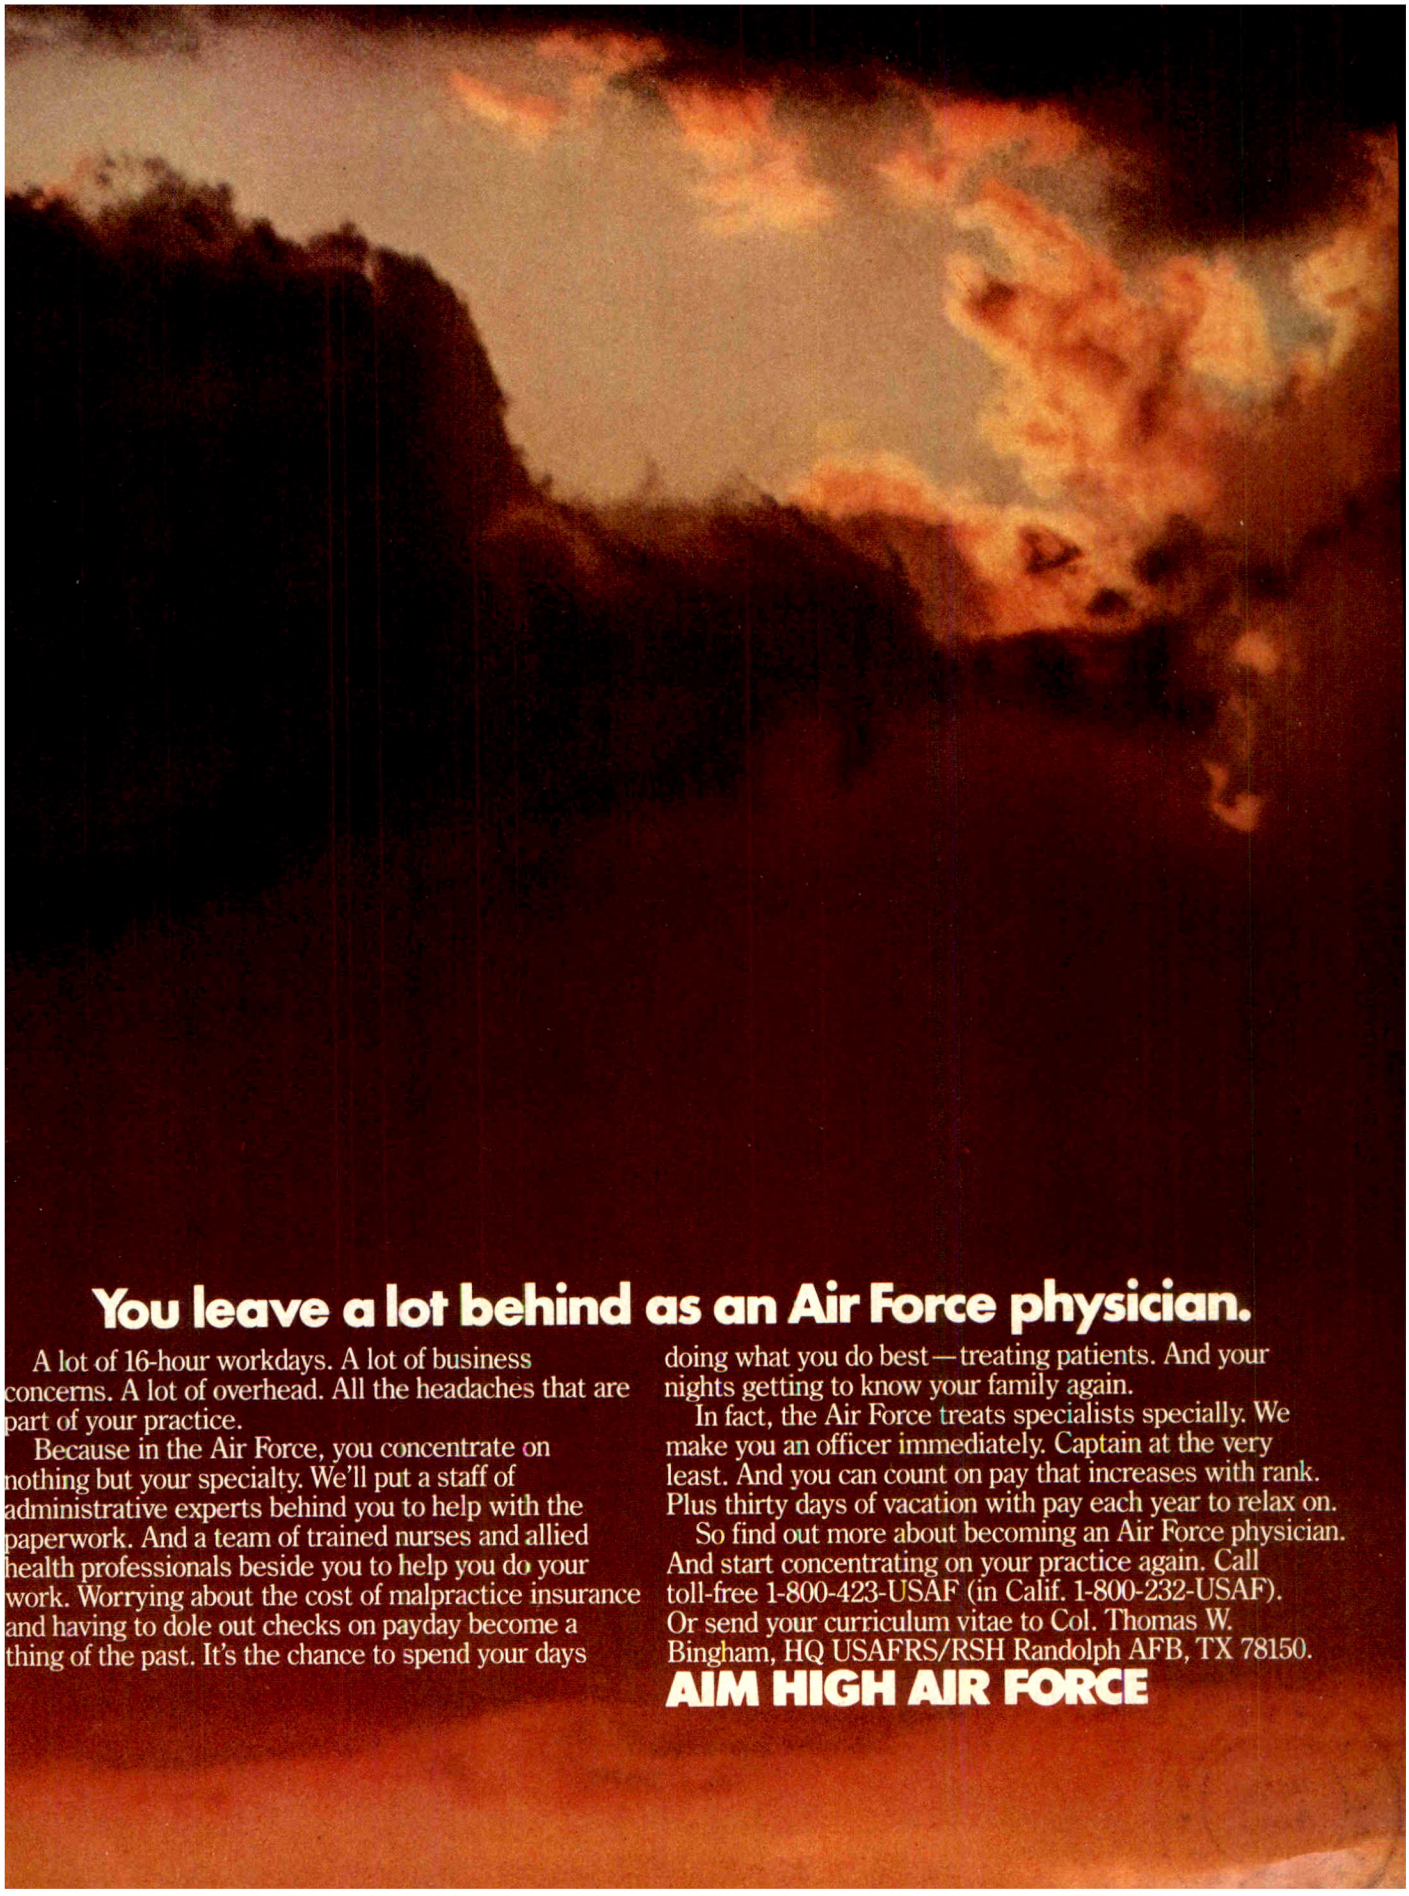
Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.



Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

You leave a lot behind as an Air Force physician.

A lot of 16-hour workdays. A lot of business concerns. A lot of overhead. All the headaches that are part of your practice.

Because in the Air Force, you concentrate on nothing but your specialty. We'll put a staff of administrative experts behind you to help with the paperwork. And a team of trained nurses and allied health professionals beside you to help you do your work. Worrying about the cost of malpractice insurance and having to dole out checks on payday become a thing of the past. It's the chance to spend your days doing what you do best—treating patients. And your nights getting to know your family again.

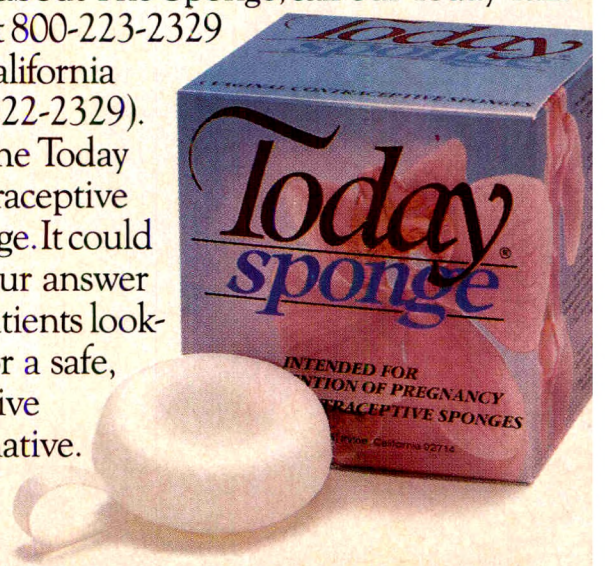
In fact, the Air Force treats specialists specially. We make you an officer immediately. Captain at the very least. And you can count on pay that increases with rank. Plus thirty days of vacation with pay each year to relax on.

So find out more about becoming an Air Force physician. And start concentrating on your practice again. Call toll-free 1-800-423-USAF (in Calif. 1-800-232-USAF). Or send your curriculum vitae to Col. Thomas W. Bingham, HQ USAFRS/RSH Randolph AFB, TX 78150.

AIM HIGH AIR FORCE

LAST YEAR, WOMEN ALL OVER THE COUNTRY STOPPED USING THEIR CONTRACEPTIVE.

And started using ours. The Today® Contraceptive Sponge.



In fact, in the three years since The Sponge™ was introduced, over 50 million have been sold. And after just one year, The Sponge was the number one over the counter female contraceptive.

Women like The Sponge because it's comfortable, disposable and easy to use. And since it's non-interruptive, it never interferes with spontaneity. While it provides protection for a full 24 hours.

It's also safe and very effective. Clinical studies showed that The Sponge has an efficacy rate of 89-91% when used correctly. When not used consistently and correctly, effectiveness was 84-87%.

If you or your patients have any questions about The Sponge, call our Today Talkline at 800-223-2329 (in California 800-222-2329).

The Today Contraceptive Sponge. It could be your answer for patients looking for a safe, effective alternative.

CLINICAL SECTION

Clinical Opinion

An obstetric approach to the prevention of early-onset group B β-hemolytic streptococcal sepsis

Howard Minkoff, M.D., and Philip Mead, M.D.

Brooklyn, New York, and Burlington, Vermont

Group B β-hemolytic streptococcus is one of the most common causes of neonatal sepsis. Despite its relationship to neonatal morbidity and mortality, no consensus exists for an approach to its prevention. Several characteristics of the organism such as high maternal carriage rates, the intermittent nature of this carriage, and the failure of antibiotics to permanently eliminate carriage have limited the success of proposed intervention protocols. In this clinical opinion we review characteristics of the organism and previously suggested intervention protocols. Then, based on this review and an analysis of recently published data, a protocol focusing on preterm births is presented. This proposal favors intrapartum treatment of all mothers who are delivered of preterm infants and who are either carriers of group B β-hemolytic streptococci or whose carriage status is unknown. A comparison of the costs and benefits of this and other approaches is made. (AM J OBSTET GYNECOL 1986;154:973-7.)

Key words: Group B β-hemolytic streptococcus, neonatal sepsis

The contribution of group B β-hemolytic streptococcus to neonatal morbidity and mortality has long been recognized and was the subject of a National Institutes of Health workshop almost a decade ago.[1] At that forum, which brought together leading investigators, "emphasis was given . . . to the definition of priorities leading to programs for the prevention of group B beta streptococcal infection." However, despite 10 years of efforts subsequent to that meeting, no consensus exists for an approach to this problem, and as recently as 1982, the published recommendation of the Centers for Disease Control for dealing with group B β-hemolytic streptococcal sepsis in *Sexually Transmitted Diseases: Treatment Guidelines* was, in toto, "the present state of knowledge about the epidemiology of group B streptococcal disease is not sufficient to recommend routine treatment of pregnant women or their sexual partners or routine prophylaxis of their newborn."[2] Without a recommended approach, a wide variety of protocols exist which vary greatly in their scope and impact. The lack of a consensus approach to group B β-hemolytic streptococcal sepsis stands in sharp contradistinction to the management of other infectious diseases that command large investments or resources and man-hours. The disparate nature of the approaches to perinatal infections is best illustrated by the current management of herpes simplex virus in contrast to that of group B β-hemolytic streptococcal sepsis.

It is estimated that herpes simplex virus infects only 120 to 1000 neonates annually in the United States. Seventy percent of these infants die, and many survivors suffer serious sequelae. Current perinatal management involves study of weekly viral cultures in the third trimester and use of cesarean section for viral shedders at term. Though this approach has been noted to be both expensive ($53 million annually, 5000 unnecessary cesarean sections) and relatively ineffective (75% of neonates exposed to asymptomatic shedders will be missed by this protocol), it remains the de facto standard of care.[3]

For group B β-hemolytic streptococcus, on the other hand, it has been estimated that 12,000 to 15,000 newborn infants per year are infected and that the mortality rate for early-onset disease can be as high as 50% among

From the Department of Obstetrics and Gynecology, State University of New York–Downstate Medical Center, and the Medical Center Hospital of Vermont.

Reprint requests: Howard Minkoff, M.D., State University of New York–Downstate Medical Center, 450 Clarkson Ave., Brooklyn, NY 11203.

premature infants.[4] Hence the number of neonatal deaths from it is several times higher than from herpes simplex virus. Yet, although many antepartum protocols for the prevention of group B β-hemolytic streptococcal sepsis have been proposed, none has been uniformly adopted because each has problems that have been clearly recognized and that may limit the benefits. Thus the lack of an ideal system has until now precluded the universal institution of any management plan, leaving the broad scope of the problem largely unaddressed.

Clearly there is a need for further research, which has been acknowledged for many years and was the focus of the National Institutes of Health workshop mentioned previously. However, although a protocol should be based on the results of a prospective randomized study, there is need for a standard approach to the prevention of group B β-hemolytic streptococcal infection until such research is completed. A study seeking to document the effectiveness of a protocol in lowering sepsis rates among preterm infants from 1% to 0.5%, for example, would have to involve a population base of over 100,000 deliveries (assuming a 9% prematurity rate) and hence probably will not be reported in the near future. Therefore, in an attempt to generate a consensus protocol that may prevent a proportion of deaths from group B β-hemolytic streptococcal disease in the interval until a more universal solution is devised (for example, vaccine), we will summarize current approaches that have been proposed as well as their shortcomings and then offer, as a clinical apinion, a management plan that would be immediately applicable and practical.

Characteristics of group B β-hemolytic streptococcal disease

Many characteristics of group B β-hemolytic streptococcal disease make it particularly insidious and difficult to eradicate. First, since up to 30% of pregnant women may be colonized, therapeutic plans directed at all group B β-hemolytic streptococcus carriers must be very broad based. Further, there are several types of carriage that can occur during pregnancy. Only 40% of colonized patients carry the organisms chronically throughout pregnancy, whereas the rest carry it either intermittently or transiently and may have a different culture status at delivery than they had antepartum. The culture characteristics of the organism also pose potential difficulties. If selective media is used, the percentage of patients who are found to be carriers will be more than double that found with standard media. These additional patients, colonized by low numbers of organisms, may not be at as significant a risk of infecting their infants. Colonization rates also vary depending on the site at which the culture is performed. There is a gradient of colonization, with the highest rates found near the rectum and progressively lower rates found toward the cervix and urethra. Infants may be infected even if the mother is colonized only in the rectum.[5]

Between 50% and 70% of women who are colonized with group B β-hemolytic streptococcal organisms will deliver infants who will also be colonized, and 1% of these colonized infants will become septic. The mortality from group B β-hemolytic streptococcal sepsis is closely linked to the gestational age of the neonate, with up to 90% of extremely premature infants but less than 5% of term infants dying. Compounding management problems is the fact that death frequently occurs despite early institution of appropriate antibiotic therapy. In addition to a higher mortality rate, an increased attack rate has been linked with prematurity. The attack rate among preterm infants is seven times that among mature infants.[4] Most neonatal deaths are a result of early-onset disease that has been associated with transmission of group B β-hemolytic streptococcal organisms from the mother's genital tract occurring either concomitantly with labor and ruptured membranes or during parturition. Thus high colonization rates, variable patterns and sites of carriage, and the relatively small percentage of colonized mothers being delivered of septic infants have made group B β-hemolytic streptococcal disease a difficult one to prevent. However, several approaches have been suggested.

Management protocols

Maternal antepartum protocol. In general, treatment schemes have been directed either at identifying and treating colonized mothers or identifying and treating colonized infants. One of the first treatment plans proposed which was directed at mothers involved culture studies of all women in the third trimester and treatment of those who were colonized to prevent them from infecting their babies at birth. The major problem with this approach was the failure of therapeutic doses of penicillin, administered to the patient and her sexual partner, to eradicate the organism, perhaps because of penicillin's decreased effectiveness in the lactamase-rich environment of the rectal flora.[6] Additionally, some patients who are not culture positive at initial testing may become culture positive at term. Finally, there may be a high rate of false negative cultures if nonselective media is used and inappropriate sites for culturing are chosen. Even if this modality of therapy were to prove effective, concern would still be raised about the number of people requiring treatment (all colonized women and their sexual partners) and the cost and risks (5% rate of adverse reactions to penicillin, 0.04% anaphylactic reaction rate) of such wide-scale antibiotic therapy.

Maternal intrapartum protocol. An alternative sug-

gestion was to identify the patient who is a carrier but then to withhold treatment until labor commences. This bypassed the problem of recolonization after earlier therapy. Further, there is evidence that intrapartum therapy, even if instituted only 2 hours before birth, can reduce or prevent neonatal sepsis. Yow et al.[7] noted no colonization among 34 infants of colonized mothers treated in labor, compared to colonization in eight of 16 infants of untreated colonized mothers. Colonized infants of treated mothers may also have lower inoculums of bacteria and lesser likelihood of sepsis. The problem with this plan is, again, that patients who are culture negative at initial screening may be positive at term and vice versa. Finally, the volume of patients who would need treatment and established infections prior to therapy remain problems.

To circumvent those problems that arise because of changes in culture status between initial cultures and labor, rapid identification techniques are being developed. Unfortunately, in the bacterial-rich vaginal environment, most techniques need long incubation periods to achieve high specificity and sensitivity. For example, Boyer et al.[8] found with use of a fluorescent antibody technique that 18 hours were needed before over 90% of carriers could be identified. Further, although the more heavily colonized mothers were identified earlier, the mothers of infants who became septic were not identified before the delivery of those neonates. Finally, even if a perfectly sensitive and specific rapid-culturing technique were available and carriers could be treated in labor, there still would be a need to treat up to 30% of all parturients.

Neonatal protocol. A report in the *Mount Sinai Journal of Medicine* gave impetus to consideration of treatment of the neonate instead of the mother.[9] That report noted that when hospital policy was switched from use of silver nitrate to intramuscular penicillin for prevention of gonococcal ophthalmia, a coincident disappearance of early-onset group B β-hemolytic streptococcal sepsis was noted. This was a retrospective report and covered some time periods (back to 1952) when the pathologic diagnosis of group B β-hemolytic streptococcal sepsis may not have been uniformly made. Although Lloyd et al.[10] subsequently reported similar findings, his study also used historic controls and the colonization rate in his treatment period was so low that one would not have expected as much morbidity as in the historic control period. Ramamurthy et al.[11] in a prospective controlled trial found no improvement with use of penicillin prophylaxis in newborn infants and noted that large fluctuations over time in colonization rates made studies of group B β-hemolytic streptococcal disease singularly inappropriate for historic controls. Siegel et al.[12] performed a 2-year prospective study in which infants delivered on alternate weeks received either intramuscular aqueous penicillin G or ocular topical tetracycline. Although the penicillin group had less group B β-hemolytic streptococcal sepsis, they had more infections with penicillin-resistant organisms. Finally, evidence that up to two thirds of infants with group B β-hemolytic streptococcal sepsis are bacteremic at birth suggests that neonatal therapy may not be the best option.[4]

Vaccines have also been considered as a potential answer to the problem of group B β-hemolytic streptococcal sepsis.[13] Mothers of infants with this sepsis are significantly less likely to have high levels of antibody than mothers of noninfected neonates. This fact has fostered the belief that immunoprophylaxis will be the ultimate solution to this dilemma. Although studies in lower animals have been encouraging, only limited success has been noted with passive or active immunization in rhesus monkeys or humans.

Proposed management

As previously mentioned, the high rates of carriage of group B β-hemolytic streptococcal disease, the frequently intermittent nature of its carriage in pregnancy, its recurrence after appropriate therapy, and the failure of antibiotics in the face of established infection in the neonate have combined to frustrate attempts to safely eradicate neonatal disease. Protocols aimed at all carriers of disease are extremely treatment-inefficient, whereas the more focused protocols that are directed at infected neonates are usually instituted too late to be successful. To be more efficient and more timely, the focus of intervention should remain on the mother yet be narrowed from being on all carriers to high-risk carriers only. After reviewing their data at the Medical Center of Vermont, Pasnick et al.[14] suggested that "an alternative approach to these problems would be the identification of risk factors for early onset disease and treatment of only those . . . at high risk." A major step in the direction of developing a focused maternal intervention protocol is based on the work of Boyer and his colleagues.[4, 5, 15] After performing exhaustive studies on maternal-fetal transmission of group B β-hemolytic streptococcal organisms,[5] carriage patterns,[15] and the chemotherapeutic impact of intrapartum antibiotics,[16] they proposed a plan based on antepartum screening and intrapartum treatment. Their proposal would result in the treatment of only 3% of all patients by aiming solely at patients who are both colonized (16.7% of their population) and who have risk factors for an increased attack rate (18.3% of their population—those with low birth weight, rupture of membranes at >18 hours, or intrapartum fever). The data of Pasnick et al.[14] noted group B β-hemolytic streptococcal morbidity in the same subgroups. Boyer subsequently documented the efficacy of this approach in a study of intrapartum use

of ampicillin. Although their work represents an impressive body of data in support of intrapartum treatment of risk patients, several concerns about the practicality of routine institution of this approach remain.

The first problem with their specific plan is that although it narrows the focus of therapy it still requires the institution of universal screening, which reduces the chances of its being widely accepted. Costs would be high, since their results are based on screening all patients with both vaginal and rectal cultures and use of selective media. Based on current costs for cultures and therapy, projected to involve >3.6 million births annually, the cost would be $108 million for universal screening and $2 million for treatment with ampicillin for 3% of all women. The second problem is that therapy is based on results of screening performed at 26 to 28 weeks. In indigent populations, which have higher prematurity rates and higher attack rates for group B β-hemolytic streptococcal disease, many patients will present in the third trimester or in labor for initial care and will not have culture results available. Also, carriage status may change between the time of culture and labor. Boyer found that the overall predictive value of a positive prenatal culture was 67.2% and that 8.5% of patients who were initially culture negative became culture positive by term. Further, the number of patients becoming positive after negative prenatal screens would be substantially higher if rectal cultures were not performed on all prenatal patients. Again, the efforts and costs involved in instituting vaginal and rectal cultures on all patients makes adaptation of this protocol unlikely. Finally, if screening is performed at an average of 27 weeks and if we assume that all results are available at the patient's subsequent visit, then a large percentage of patients whose neonates will die with group B β-hemolytic streptococcal sepsis will be born before results are available (in Boyer's study, one half of all deaths were among infants under 1000 gm). If cultures are done earlier to surmount that problem, then the predictive abilities of prenatal screens, cited above, would be further compromised. Despite these problems Boyer's work represents an important step toward developing a practical approach to this major problem.

The approach that we propose in this clinical opinion would result in a slight increase in the number of parturients receiving antibiotics in labor while substantially reducing the number of patients needing screening, hence minimizing the logistic complexities that universal screening entails. Among the groups at high risk for sepsis as delineated by Boyer, we would focus on preterm infants. Approximately 93% (15 of 16 in Boyer's study) of neonatal deaths associated with group B β-hemolytic streptococcal early-onset disease occurred in that group. Patients with chorioamnionitis, one of the other risk groups, routinely receive antibiotics independent of group B β-hemolytic streptococcal culture status. Attempting to treat the final risk group, all culture-positive term patients with ruptured membranes >18 hours would reduce the total number of deaths associated with group B β-hemolytic streptococcal disease only slightly while requiring a tremendous increase in the need to obtain cultures as well as timely results. Further, since sepsis in their study occurred at or beyond 18 hours of the rupture of the membranes, it would be necessary to start therapy earlier in the course of labor to prevent morbidity and hence would necessitate therapy of a markedly increased percentage of patients once the focus expanded from patients with rupture >18 hours to those patients who may eventually have rupture >18 hours.

We suggest that for all patients admitted in preterm labor and/or with preterm premature rupture of membranes (<37 weeks' gestation), cultures for group B β-hemolytic streptococcal disease be obtained. If labor is successfully inhibited with tocolysis, antibiotic therapy can be withheld pending culture results. All culture-positive patients should be treated with ampicillin (2 gm every 6 hours for 24 hours, then switched to 500 mg every 6 hours orally for 2 weeks, and then recultured; erythromycin is used for the penicillin-allergic patient). If the patient's labor is not successfully inhibited and the culture result is pending, then antibiotic therapy is begun. If a patient being managed conservatively with preterm ruptured membranes goes into labor (assuming tocolysis is not used), antibiotics are given if the culture is pending (2 gm intravenously as soon as possible, then 2 gm every 6 hours). Thus all therapy and culturing is reserved for the approximately 8.9% of the population who deliver prematurely and who account for over 90% of group B β-hemolytic streptococci–associated deaths. The actual number receiving therapy may even be less, depending on the number of patients whose labor is successfully inhibited while culture results are pending. Although a large number of culture-negative patients will receive unnecessary antibiotics because of unavailable culture results, at the most this number represents approximately 7.5% of all patients (prematurity rate, 8.9% times the culture-negative rate, or 83.3% in Boyer's work) which is not markedly different from the approximately 6% of patients who would receive unnecessary therapy when all risk groups that are culture positive at 26 to 28 weeks are treated in labor (18.3%, total of all risk groups, times 32.8%, patients positive at prenatal visit but not positive during delivery). The slightly increased need for therapy is balanced against a substantial decrease in the number of patients requiring cultures and the number of patients not receiving needed therapy,

because although their culture status was positive during delivery, it was negative at initial screening (8.5% of risk patients). Perhaps most critically, this system would be simple to implement. Finally, if simple, accurate, rapid diagnostic tests for group B β-hemolytic streptococcal disease become readily available, then the number of patients receiving unnecessary therapy because culture results are not available would markedly decline. If the protocol is instituted, it is imperative that hospitals using it keep a careful record of all neonatal deaths attributable to sepsis so that failures related to parochial resistance patterns, established infection, or other problems are quickly detected.

An important question that remains is the safety of waiting for culture results for the preterm patient with ruptured membranes being managed conservatively. Unfortunately, the risk of ascending infection with group B β-hemolytic streptococcus during the time that culture results are pending is unknown. If rapid screening were available, risks could be minimized, since antibiotics could be instituted within hours of rupture. Without rapid screening it is necessary to consider initiating use of prophylactic antibiotics on admission for patients with premature rupture of membranes. However, the risk/benefits ratio of that approach is difficult to assess pending the results of studies currently under way.

This paper does not address the question of group B β-hemolytic streptococcal disease as a cause of preterm labor or premature rupture of membranes. Various authors have reported divergent results on that subject[4, 16] and the potential benefit of treating group B β-hemolytic streptococcal disease to prevent preterm labor or premature rupture of membranes has not yet been demonstrated. Unless that can be clearly shown, we believe that focusing on patients with preterm infants and treating either those with culture results positive for group B β-hemolytic streptococcal disease or those whose culture status is unknown is a reasonable protocol with which to begin to address a neonatal disease that far surpasses herpes simplex virus as a cause of perinatal mortality. As for concern about obscuring the diagnosis of neonatal disease among infants born to antibiotic-treated mothers, we concur with Boyer's statement that "when there is a substantial and well-defined risk of intrauterine infection, the potential benefit of intrapartum prophylaxis for the newborn infant more than compensates for increased uncertainty in postnatal diagnosis." Finally, although we also agree that "the possibility of selecting resistant flora by blanket use of prophylaxis remains a disturbing risk" and that "additional controlled data documenting safety and efficacy of selected intrapartum chemoprophylaxis in preventing invasive disease will be required before a firm recommendation can be made," it is our clinical opinion that in this particular population, our therapeutic strategy is warranted while the aforementioned studies are ongoing.

Perinatal events and cerebral palsy

Paul A. Hensleigh, M.D., Ph.D., Theodore Fainstat, M.D., Ph.D., and Roger Spencer, M.D.
San Jose, California

This review highlights recent studies that refute the following hypothesis on the genesis of cerebral palsy: The risk factors that cause death are also risk factors for brain damage resulting in cerebral palsy, if they occur at lower intensity, less frequently, or for a shorter duration. Untested, unproved, and invalid theories that emerged in the 1950s stimulated the assembly of much data that are at odds with the notion that the pathways of causation for cerebral palsy and perinatal mortality are identical. (AM J OBSTET GYNECOL 1986;154:978-81.)

Key words: Cerebral palsy, brain damage, birth injury, asphyxia neonatorum, perinatal morbidity

More than a century ago Little[1] associated a group of childhood "deformities" and mental states with asphyxia neonatorum, abnormal parturition, difficult labors, and premature birth. Significant efforts to further link these events to the cause of abnormal human neurological development have included refined epidemiologic studies and experiments with animal models. Even so, the pregnancy or labor conditions that will predictably result in defects, such as cerebral palsy, are not established.

In 1951, Lillienfeld and Parkhurst[2] offered a unifying hypothesis of common causation for both perinatal mortality and cerebral palsy. This was based on their analysis of the initial data from the New York Crippled Children's Program. They postulated the existence of a "continuum of reproductive wastage" with lethal and sublethal manifestations. The lethal component included abortions, stillbirths, and neonatal deaths. The sublethal component included cerebral palsy and possibly other disabilities. From this analysis, the authors suggested that the preventive aspect of a cerebral palsy program should be placed within the general scope of a maternal health program. Thus they extended the hypothesis to include a continuum of causation and prevention, implying that obstetric innovations that brought about improvements in perinatal mortality would also reduce the frequency of occurrence of cerebral palsy and related conditions. Subsequently, the obstetric and pediatric literature has accepted the concept of a common causation of perinatal mortality and cerebral palsy to the point that it is essentially dogma.

It should now be pointed out that much data are currently available that are at odds with the notion that the pathways of causation for cerebral palsy and perinatal mortality are identical. In fact, there may be only a few common factors among many that are disparate. This review will highlight recent studies which refute the following hypothesis on the genesis of cerebral palsy: The risk factors that cause death are also risk factors for brain damage resulting in cerebral palsy, if they occur at lower intensity, less frequently, or for a shorter duration.

Animal models of cerebral palsy

Brain damage induced by either chronic or acute hypoxia in rhesus monkeys demonstrates specificity regarding the site of damage and the pattern of the abnormality according to the time course of induced hypoxia.[3] It was at first surprising and later striking that attempts to regularly produce a clinical picture like cerebral palsy in these animals was not successful. In most cases, the fetuses either survived experimental asphyxia and were neurologically intact or they died.

An alternative strategy by Clapp et al.[4] involves a search for experimental conditions in the fetal sheep model to induce brain damage without producing hypoxia or acidosis. Two sets of perturbations in this animal model were shown to cause histologic damage in cortical white matter. The first involved partial (20% to 80%), intermittent (10 seconds on, 10 seconds off) umbilical cord occlusion for 1 of every 3 minutes for a total duration of 2 hours during late gestation. In a second group of animals growth retardation of the fetus was produced by embolization of the uterine circulation, a previously described procedure that does not cause brain damage. Subsequently, however, the brain was indeed damaged when mild hyperglycemia was produced in the fetuses by raising the blood glucose from about 20 to 40 mg/100 ml for 4 hours in late gestation. Neither of these experimental conditions resulted in fetal deaths or even evidence of significant fetal hypoxia or acidosis.

Recent studies on intracerebral hemorrhage in both term and preterm human fetuses have also focused on

the dominant role of fluctuating cerebral blood flow in determining the incidence and severity of hemorrhage.[5, 6] Especially the more severe hemorrhages are associated with subsequent impaired neurological development. These studies suggest that transient shifts in blood flow, while generally not linked to fetal or neonatal death, may contribute substantially to intracranial hemorrhage and brain damage.

Epidemiology of cerebral palsy and perinatal mortality

The incidence of cerebral palsy in developed countries is about 1.5 to 2.5 per 1000. Comparisons between countries show no correlation with the prevailing perinatal mortality rate.[7] Differences in the absolute incidence are often attributable to the definitions and study criteria used rather than to the populations. The great improvement in perinatal mortality of the last 25 years has been accompanied by an essentially unchanged incidence of cerebral palsy. During the course of the United States Collaborative Perinatal Project (1959 to 1966) and also through the course of a Swedish study extending from 1958 through 1976, there were substantial reductions in perinatal mortality but a conspicuous lack of parallel decreases in cerebral palsy.[7, 8] A somewhat different trend was seen in the data from the Western Australian cerebral palsy register.[9] From 1961 through 1975, there was a downward trend in cerebral palsy incidences for heavier infants (>2500 gm) whereas the rate remained steady among low birth weight infants. Although this phenomenon has not been confirmed in other reports, recent improvements in survival of very low birth weight infants could make it difficult to identify a falling incidence of cerebral palsy occurring only in larger infants.

The magnitude of the confounding effect of increased and increasing numbers of preterm deliveries can be estimated with the recently published data of Shennan et al.[10] and Milligan et al.[11] from the Regional Perinatal Unit, Women's College Hospital, Toronto, Ontario, Canada. For births occurring in 1979 through 1982, there were 383 live births with gestations between 26 and 30 weeks. At 1 year there were 349 surviving children, of whom 27 (about 8%) had cerebral palsy. Twelve of these 27 children had either severe motor disability or mental retardation in addition to motor disability. Deliveries occurring before completion of 30 weeks' gestation constitute about 0.5% of total live births.* Cerebral palsy in 8% of these very preterm infants would contribute 0.4 per 1000 to the overall population incidence of cerebral palsy. In the last decade several tertiary units have shown a doubling of survival for infants born at this early gestational age. In the example above, half of the cerebral palsy cases in deliveries at 26 to 30 weeks' gestation may be attributed to the recently increased survival of very preterm babies, and this increment would constitute an additional 0.2 per 1000 to the overall population incidence. This potential confounding effect could constitute about 10% of the prevailing incidence. If the vast improvement in overall perinatal mortality during recent years were accompanied by similar reductions in cerebral palsy, this small influence due to increased survival of very small infants should not obscure the expected decreased incidence of cerebral palsy.

Another observation among children followed up until age 7 in the United States Collaborative Perinatal Project was the higher incidence of cerebral palsy in white children (6.0 per 1000) than in black children (4.3 per 1000).[7] These rates are statistically different and there is obvious discordance with preterm births and perinatal mortality, both of which are more frequent in black children.

Poor correlation between asphyxia and occurrence of cerebral palsy

The Collaborative Perinatal Project data show a relationship between low Apgar scores and cerebral palsy only when there are very low Apgar scores for prolonged periods.[12] Table I shows that for infants with Apgar scores of ≤3 beyond 5 minutes, there is a linear relationship between the percentage of survivors with cerebral palsy (among infants >2500 gm) and duration of low score. However, in the same data it is evident that a clear majority (73%) of children who developed cerebral palsy had 5-minute Apgar scores of ≥7. Thus the 5-minute Apgar score is neither sensitive nor specific in predicting cerebral palsy.

A major argument for use of fetal heart rate monitoring in labor has been the ability to recognize fetal distress patterns associated with intrapartum and neonatal mortality. A similar correlation has not been made with postpartum neurological or brain injury. Painter et al.[13] have followed the neurological development of a group of children who had late or severe variable fetal heart rate decelerations during labor. Forty-five of the original 50 patients were examined at age 6 to 9 years. Detailed neurological examinations showed that all were normal except for one child with a genetic syndrome who demonstrated persistent late decelerations in labor.

Similarly, the physical and mental development in infants delivered after a positive contraction stress test has been reported by Crane et al.[14] Although the 12 subjects compose a small sample and the follow-up ranges from only 5.5 months to 4.75 years, the results are encouraging. No major neurological abnormalities

Table I. Collaborative Perinatal Project data on Apgar scores and cerebral palsy by birth weight

	<2500 gm		>2500 gm	
	Survivors with cerebral palsy (%)	*No. of cerebral palsy cases*	*Survivors with cerebral palsy (%)*	*No. of cerebral palsy cases*
1 min Apgar score 7-10	0.6	13	0.2	53
1 min Apgar score 0-3	2.9	9	1.5	22
5 min Apgar score 0-3	6.7	5	4.7	13*
10 min Apgar score 0-3	3.7	1	16.7	11
15 min Apgar score 0-3	0	0	36.0	9
20 min Apgar score 0-3	0	0	57.1	8

*A total of 73% of individuals with cerebral palsy had 5-minute Apgar scores of ≥7.

were detected and 10 of the 12 displayed normal mental and motor function, as determined by the Denver Development Screening Test, Bayley Scales of Infant Development, and Wechsler Preschool and Primary Scale of Intelligence. The two exceptions were infants with additional serious neonatal complications who scored poorly only on the Bayley test.

Another report on severe acidemia at birth in The Netherlands provides the follow-up neurological examinations from 2.5 to 5 years on 24 normally grown infants delivered at term who had no birth trauma or birth defects.[15] The umbilical blood pH of all infants was ≤7.0. Major neurological abnormalities were not found in this group, but three infants were classified as neurologically "suspect" because of mild to moderate hypotonia. A comparison group of 115 nonacidemic infants who met the same selection criteria also had follow-up examinations that yielded 10.5% neurologically "suspect" or abnormal children. They concluded that acidemia itself is not a major cause or predictor of later neurological abnormalities in normally grown term infants.

Evidence for multifactoral causation of cerebral palsy and noncorrelation of cerebral palsy with causation of perinatal morality

The analysis by Lillienfeld and Parkhurst,[2] which led them to formally state the "continuum of reproductive wastage" hypothesis, focused on the fact that in pregnancies resulting in infant loss and producing children with cerebral palsy, some of the same pregnancy complications occurred. Complications having similarly increased frequencies in these two adverse outcome groups included placenta previa, breech and other malpresentations, and dystocia.

However, there were many complications that had markedly discrepant frequencies between pregnancies with perinatal mortality and pregnancies resulting in birth of a child with cerebral palsy. Premature separation of the placenta, complications of the umbilical cord, bleeding during pregnancy, and toxemia were much more closely associated with infant loss. Deviations of the bony pelvis were more frequently associated with the delivery of an infant with cerebral palsy. Their data could clearly form the basis for a very different conclusion than the one they proposed.

Their data and numerous subsequent studies show that many and diverse conditions and perinatal events occur with increased frequency in pregnancies with a disappointing neonatal outcome. One might have argued that these two categories of adverse outcomes, cerebral palsy and perinatal death, are each unique in regard to their many associated and possibly causative conditions. Among the linked causes for each, there may be a small common domain.

The analysis of perinatal factors associated with death or neurological handicap in preterm infants by Shennan et al.[10] makes this point even more clearly. The clinical events for infants who died were compared to those for surviving normal infants who were born at the same gestational age (between 26 and 30 weeks). Mothers of infants who died were less likely to have been in preterm labor and to have received betamethasone. The fetuses who died were less likely to have had a normal heart rate pattern and were more likely to be male. Statistically significant correlations with death in the newborn period included low 5-minute Apgar score, low venous cord pH, cord blood base deficit, low blood pressure in the first 72 hours of life, and occurrence of respiratory distress syndrome. In addition there was a direct relationship between gestational age at birth and probability of survival.

In marked contrast, none of the 18 obstetric factors analyzed occurred at higher frequency in women who were delivered of a child with a subsequent major neurological handicap. Among the 23 neonatal factors studied, handicapped infants were statistically different from control infants only in the maximum oxygen concentration and respiratory rate required. The only common factor associated at increased frequency with both death and handicap in this study was intraventricular hemorrhage in the newborn period. The conclusion of this study is clearly stated by the authors: ". . . contrary to our traditional understanding, there is

a difference between the factors leading to death of the newborn infant and those leading to damage in survivors at the same gestational age."[10]

Perinatal mortality rates have greatly improved since obstetricians implemented preventive approaches that utilize the current diagnostic tests available for fetal growth and well-being in the antepartum period in addition to fetal heart rate monitoring during labor. Obstetricians have assumed that the strategy of applying these same diagnostic innovations could lead to marked improvements in the occurrence of brain damage among surviving infants. However, the prevention of neurological damage and the anticipated decline in cerebral palsy have not occurred.

Prematurity and asphyxia are definitely associated with cerebral palsy. What we presently lack is an understanding of the underlying conditions responsible for brain injury when the infant is born prematurely or when asphyxia occurs despite our best efforts. In this regard, preventive programs may remain unsuccessful until the causation of cerebral palsy is more fully understood. While we have learned much about causation and prevention of perinatal mortality, very little has been established about the causation and prevention of cerebral palsy.

Human papillomavirus infection of the cervix detected by cervicovaginal lavage and molecular hybridization: Correlation with biopsy results and Papanicolaou smear

Robert D. Burk, M.D., Anna S. Kadish, M.D., Servio Calderin, M.D., and Seymour L. Romney, M.D.

Bronx, New York

Human papillomaviruses have previously been identified by molecular hybridization in the majority of dysplastic and cancerous lesions of the cervix. Since human papillomavirus types 16 and 18 have been strongly associated with cervical cancer, the identification of patients infected with these specific human papillomavirus types may provide useful prognostic information. We have developed a painless, noninvasive cervicovaginal lavage technique to collect exfoliated cervicovaginal cells, which can be reliably analyzed for the presence of human papillomavirus deoxyribonucleic acid by Southern blot analysis with the use of deoxyribonucleic acid cloned from human papillomaviruses 6, 11, 16, and 18. In a prospective study of 60 women referred to a colposcopy clinic for evaluation of abnormal Papanicolaou smears, we have detected human papillomavirus deoxyribonucleic acid in 16 of 17 (94%) women with a Class III (dysplasia) or IV (carcinoma in situ) Papanicolaou smear, five of 11 (45%) women with a Class II (atypical) Papanicolaou smear, and 10 of 34 (29%) women with a normal Papanicolaou smear. Detection of human papillomavirus deoxyribonucleic acid in cervicovaginal cells was indicative of a dysplastic cervical lesion in 19 of 20 (95%) patients irrespective of Papanicolaou smear results. We conclude that human papillomavirus deoxyribonucleic acid analysis in cervicovaginal cells is a sensitive method to detect dysplastic lesions of the cervix and may be useful in identifying patients with specific types of human papillomavirus infection, who are at risk to develop cervical cancer. (Am J Obstet Gynecol 1986;154:982-9.)

Key words: HPV, cervical dysplasia, Pap smear

The human papillomaviruses are a heterogeneous group of small double-stranded circular deoxyribonucleic acid (DNA) viruses that infect the squamous epithelium of man and produce a variety of proliferative diseases (reviewed in references 1 and 2). Recent advances in recombinant DNA technology have allowed the molecular cloning of more than 30 different types of human papillomaviruses. With the use of DNA hybridization, at least four different human papillomavirus types, 6, 11, 16, and 18, have been identified in tissue originating from cervical and genital lesions.[2, 3] HPV types 6 and 11 are frequently identified in benign genital and cervical warts, whereas human papillomavirus types 16 and 18 are the predominant types found in cervical and genital carcinomas.[2, 3] Human papillomavirus type 16 DNA has also been identified in high-grade dysplastic lesions of the cervix.[4] Not only are human papillomaviruses 16 and 18 DNA sequences present in cervical cancer cells, but they are also transcriptionally active both in cultured cervical cancer cells and in fresh tumor tissue.[5] DNA sequences of human papillomaviruses types 16 and 18 are frequently integrated into the genomes of cervical cancer cells, whereas they exist as episomal plasmids in most premalignant cervical lesions.[2, 5] Thus specific types of human papillomaviruses are found in both invasive and preinvasive lesions of the cervix. Furthermore, accu-

mulating evidence is incriminating specific types of these viruses as potential oncogenic agents in cervical cancer.

Exfoliative cervicovaginal cytologic (Papanicolaou) testing is an effective method for detecting dysplastic (cervical intraepithelial neoplasia) and malignant cervical cells. The technique has become widely used as a cancer screening test. Unfortunately, the biologic behavior of precancerous lesions from which cells exfoliate cannot be predicted on the basis of morphologic features alone.[6] This clinical dilemma is related to the fact that although a large proportion of cervical intraepithelial neoplastic lesions may take many years to progress, some may fail to progress or may even regress.[6] Moreover, other cervical intraepithelial neoplasia can be aggressive and rapidly progress to invasive carcinoma. Women with rapidly progressive lesions are rarely identified by periodic Papanicolaou smears before the development of invasive cancer.[7-9] While large-scale cervical cancer screening programs have reduced deaths from invasive cancer, there are a significant number of women who have undetected lesions despite regular cytologic examination.[7,8] Moreover, a single Papanicolaou smear from a patient with a cervical lesion may be negative due either to inadequate sampling of exfoliated cells or to incorrect cytologic interpretation (reviewed in reference 10). The false negative rate for a single Papanicolaou smear in women with histologically confirmed lesions can be as high as 50%.[10]

If, in fact, cervical cancer develops with greater frequency in women infected with specific human papillomavirus types, then the early detection of such infections could serve to identify women at risk for developing an invasive lesion. To investigate the hypothesis that infection with specific human papillomavirus types is related to the oncogenesis of cervical cancer, we have initiated a prospective study to detect human papillomavirus DNA in cervicovaginal cells from women attending a colposcopy clinic. The observation that dysplastic and condylomatous epithelial cells exfoliate readily suggested the possibility that the use of a lavage technique to collect exfoliated cells coupled with molecular hybridization for human papillomavirus DNA might provide a sensitive viral screening test.[11] We have developed a simple, noninvasive, and painless method to reliably sample cervicovaginal epithelial cells whereby human papillomavirus DNA can be detected by molecular hybridization. Since human papillomavirus infection cannot be documented by culture of virus or by serologic testing, we have compared the results of human papillomavirus DNA analysis of exfoliated cervicovaginal cells obtained by cervicovaginal lavage with the direct analysis of human papillomavirus DNA in cervical biopsy specimens. In this report, we present the results demonstrating (1) the sensitivity of detecting human papillomavirus DNA in cervicovaginal cells, (2) the general applicability of this method as a screening procedure to detect infection by specific types of human papillomavirus, and (3) the comparison of viral DNA findings to the results of cervical cytologic testing in simultaneously obtained specimens. In addition, we present evidence that the presence of human papillomavirus DNA correlates well with the presence of a dysplastic cervical lesion. The histopathologic, immunocytochemical, and ultrastructural changes induced in cervical epithelial cells by specific types of human papillomaviruses are described elsewhere.[12]

Methods

Specimens. All specimens were obtained from women attending a colposcopy clinic at the Bronx Municipal Hospital Center. New patients were referred for colposcopic evaluation after either two consecutive Class II (atypical), one Class III (suspicious), or one Class IV (positive) Papanicolaou smear. Other patients were seen for routine follow-up visits for a past history of cervical dysplasia, some of these women had been treated years ago and are considered to have been cured. A routine Papanicolaou smear was obtained and was followed by the collection of cervicovaginal fluid washings. This was accomplished by swabbing the cervix with normal saline solution and the application of a 5% acetic acid solution. Thereafter, the cervix was lavaged with approximately 7 to 8 ml of saline solution and the washings were aspirated from the posterior vaginal fornix. Colposcopic examination was performed on all patients and biopsies of abnormal-appearing areas were obtained under colposcopic vision. Adjoining biopsy specimens were sent for histopathologic diagosis and DNA analysis, respectively. Biopsy specimens for histologic examination were embedded in paraffin and stained with hematoxylin and eosin. Grading of dysplasia was done according to the World Health Organization criteria for mild, moderate, and severe dysplasia and carcinoma in situ.[13] Papanicolaou smears were evaluated for abnormal cells and reported as Class I (negative), Class II (atypical), Class III (suspicious), or Class IV (positive) by routine criteria.[11]

Molecular hybridization. Human papillomavirus types 6, 11, 16, and 18 cloned in pBR322 were generously provided by Dr. L. Gissmann, Freiburg, Federal Republic of Germany. Human papillomavirus recombinant clones were amplified and purified by standard methods.[14] The human papillomavirus DNA insert was purified from the plasmid DNA by electroelution and radiolabeled by primer extension.[14,15]

Biopsy tissue (approximately 50 mg) was placed directly in cervical biopsy solution (50 mmol/L Tris, pH 8.6, 25 mmol/L ethylenediaminetetraacetic acid (EDTA), 500 μg/ml proteinase K, and 0.2% sodium

dodecyl sulfate), heated to 60° C for 1 to 2 hours, and rotated overnight at 42° C. DNA was purified by two phenol extractions and two chloroform–isoamyl alcohol extractions. The salt concentration was adjusted to 0.2 mol/L potassium acetate and the DNA was precipitated by adding two volumes of cold absolute ethanol. The DNA was concentrated by centrifugation at 11,000 rpm for 20 minutes at 4° C, dried, and resuspended in 25 μl of TE buffer (10 mol/L Tris, pH 7.4, and 0.1 mol/L EDTA).

Exfoliated cervicovaginal epithelial cells were separated from the lavage fluid by centrifugation and resuspended in cervical biopsy solution. DNA was then isolated as described above for cervical biopsy tissue.

To detect human papillomavirus DNA, 5 to 10 μg of DNA from cervical biopsy tissue or cervicovaginal cells was digested overight with Bam HI, Eco RI, or Pst I according to manufacturer's specifications and the resultant DNA fragments were separated in 0.7% agarose slab gels by electrophoresis. The gels were stained with ethidium bromide and photographed under ultraviolet light, and the DNA was denatured and neutralized, then transferred to Zetabind membranes (Bio-Rad) according to manufacturer's specifications. The Zetabind membranes were prehybridized in 5X SCC (1X SCC = 0.15 mol/L sodium chloride and 0.015 mol/L sodium citrate), 20% deionized formamide, 50 mmol/L sodium phosphate (pH 6.5), 500 μg/ml of alkali-denatured salmon testis DNA, and 0.2% Ficoll, 0.2% polyvinylpyrrolidone, and 0.2% bovine serum albumin, at 42° C for a minimum of 8 hours. All hybridizations were performed under conditions of low stringency (to detect related human papillomavirus types): 5X SSC, 20% formamide, 50 mmol/L sodium phosphate, 250 μg/ml of salmon testis DNA, and 0.1% Ficoll, 0.1% polyvinylpyrrolidone, and 0.1% bovine serum albumin, with 5 to 10 × 10^6 cpm/ml of radiolabeled human papillomavirus DNA, specific activity 4 to 8 × 10^8 cpm/μg of DNA, for 24 to 36 hours at 42° C. After hybridization, filters were washed at 45° C under conditions of low stringency (minimum of 0.5 mol/L sodium chloride) as previously described,[15] kept moist, exposed for 24 to 48 hours at −70° C, rewashed under conditions of high stringency (0.1X SSC and 0.1% sodium dodecyl sulfate) at 60° C, kept moist, exposed for 1 to 7 days. In order to reuse membranes for subsequent hybridization with different probes, membranes were either treated with alkali according to manufacturer's suggestion or boiled in 0.1X SSPE (1X SSPE = 18 mmol/L sodium chloride, 10 mmol/L sodium phosphate, and 1 mmol/L EDTA/0.5% sodium dodecyl sulfate) for 20 minutes to remove radioactive probe. Membranes were routinely reexposed to assure that the probe had been dislodged. In addition, all filters were subsequently hybridized with radiolabeled pBR322 to ascertain that the human papillomavirus signal was in fact derived from human papillomavirus sequences. No hybridization bands were detected with radiolabeled pBR322 DNA.

Determination of human papillomavirus type was ascertained by a combination of (1) comparison of hybridization signal intensity of human papillomavirus DNA in samples with different human papillomavirus type probes and (2) restriction enzyme cleavage patterns. All samples were analyzed for human papillomavirus type without knowledge of histologic or cytologic findings.

Results

To determine the specificity and sensitivity of detecting human papillomavirus DNA in exfoliated cervicovaginal cells isolated from cervicovaginal lavage, we compared the DNA hybridization results obtained from cervicovaginal cells with those obtained from colposcopically directed biopsy tissue specimens. Sixty women were entered into the study; 29 had human papillomavirus DNA analysis of both cervical biopsy specimens and cervicovaginal cells taken during the same examination. The results of human papillomavirus DNA analysis of biopsy specimens and cervicovaginal cells from those 29 patients are shown in Table I. Twenty of the 29 (69%) patients had positive test results for human papillomavirus DNA in either cervicovaginal cells or cervicovaginal cells and cervical biopsy specimens. Fourteen (48%) patients had human papillomavirus DNA in both biopsy specimens and cervicovaginal cells; six (21%) patients had human papillomaviruses DNA detectable in cervicovaginal cells but not in the cervical biopsy specimens; and nine (31%) patients had no detectable human papillomavirus DNA in either biopsy specimens or cervicovaginal cells. In no case was DNA found in a biopsy specimen but not in cervicovaginal cells.

An example of an experiment determining the presence and type of human papillomavirus DNA in cervical biopsy specimens and cervicovaginal cells is shown in Fig. 1. DNA isolated from specimens obtained from two patients was digested with Bam HI, and Southern

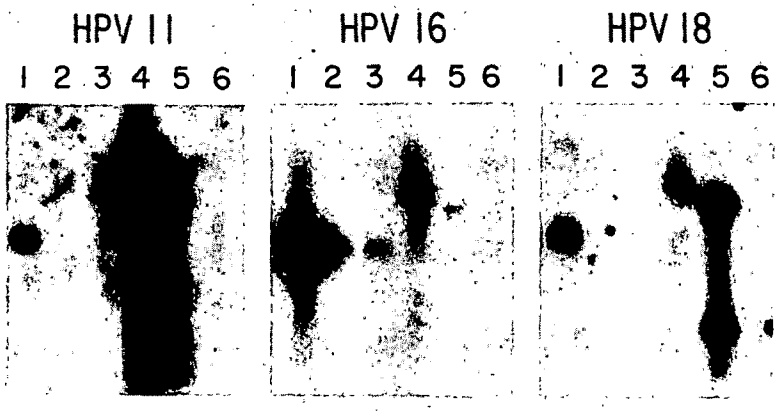

Fig. 1. Comparison and typing of human papillomavirus DNA in cervical biopsy specimens and washings from two patients. DNA isolated from two cervical biopsy specimens (lanes *1* and *2*) and the exfoliated cervicovaginal cells from lavage (lane *3*) of Patient B. G. and from cervical biopsy (lane *4*) and cervicovaginal (lane *5*) of Patient D. B. were digested with Bam HI, and a Southern blot experiment was done. The same membrane was sequentially hybridized with four different types of radiolabeled human papillomavirus insert deoxyribonucleic acid (only three are shown). The three panels show the results after hybridization with human papillomavirus types 11, 16, and 18 followed by stringent washing. Lane *6* contained radiolabeled lambda Hind III markers.

blot experiments were performed. The same membrane was sequentially hybridized with the four different human papillomavirus radiolabeled probes as described in Methods. The three panels show the Southern blot results after hybridization with human papillomavirus types 11, 16, and 18 after stringent washing. The DNA from biopsy specimen A of Patient B. G. (lane *1*) hybridized with all human papillomavirus types but showed the strongest hybridization with type 16, whereas the DNA from biopsy specimen B and the cervicovaginal cells of Patient B. G. (lanes *2* and *3*, respectively) showed only hybridization to type 16. Biopsy specimen A of Patient B. G. (lane *1*) hybridized with types 11 and 18 since different human papillomaviruses contain varying degrees of homologous sequences that can cross hybridize when a large quantity of human papillomavirus DNA is present in a sample specimen (see lane *4* also). Therefore, the three specimens from Patient B. G. (lanes *1* to *3*) contained human papillomavirus type 16. The DNA from the biopsy specimen of Patient D. B. (lane *4*) showed the strongest hybridization with human papillomavirus type 11, whereas the DNA from cervicovaginal cells (lane *5*) displayed two patterns of hybridization. With human papillomavirus type 11 *(left panel)* a single band similar in size to but less intense than that in lane *4* was present, and with human papillomavirus type 18 *(right panel)* two different hybridization bands were present. The two human papillomavirus type 18 hybridization bands in the cervicovaginal cells (lane *5*) represent the presence of a type 18 human papillomavirus with two Bam HI restriction sites and are characteristic of many human papillomavirus type 18 DNA samples identified to date (Burk RD, unpublished observations). Thus Patient D. B. had human papillomavirus 11 in the biopsy specimen (lane *4*) and both type 11 and type 18 in the cervicovaginal cells (lane *5*). The presence of human papillomavirus type 18 DNA in the cervicovaginal cells (lane *5*) probably resulted from a lesion in the cervix that was different from the biopsy specimen assayed (lane *4*).

Table II. Presence of human papillomavirus DNA in exfoliated cervicovaginal cells and findings of dysplasia in cervical biopsy specimens and Papanicolaou smears

Histologic results of biopsy specimen	*Papanicolaou smear*	*No. of patients with HPV DNA in cervicovaginal cells*
No abnormality	Class I	1/8*
	Class II	0/1*
	Class III/IV	1/1†
Dysplasia	Class I	6/6†
	Class II	3/3†

smear, lavage, and biopsy (Table II). There was a high correlation between the finding of dysplasia on colposcopically directed biopsy and the presence of human papillomavirus DNA in cervicovaginal cells. Of 20 patients with dysplasia found on either biopsy specimen or Papanicolaou smear, 19 (95%) had human papillomavirus DNA detected in the cervicovaginal cells. In contrast, one of nine (11%) patients with no evidence of dysplasia in the biopsy specimen or Papanicolaou smear had human papillomavirus DNA in the cervicovaginal cells. The sensitivity of human papillomavirus DNA analysis of cervicovaginal cells as a screening test is corroborated by the finding that of the 20 patients with human papillomavirus DNA identified in cervicovaginal cells, 19 (95%) were shown to have a dysplastic lesion by standard histologic and cytologic methods. In contrast, 13 of 19 (68%) patients with dysplasia found in biopsy specimens had positive (Class II to IV) Papanicolaou smears on the day of study.

The results of human papillomavirus DNA hybridization in cervicovaginal cells were then compared to Papanicolaou smear results in a larger group of patients, some of whom had not undergone cervical biopsy analysis (Table III). Fifty-eight patients had one and two patients had two Papanicolaou smear and cervicovaginal cell specimens analyzed. Twenty-eight of 60 (47%) women had abnormal Papanicolaou smears and 32 of 60 (53%) had negative Papanicolaou smears on the day of study (Table III). In the 11 patients with Class II Papanicolaou smears, five (45%) had human papillomavirus DNA in the cervicovaginal cells. Of the 17 patients with Class III or Class IV smears, 16 (94%) had positive human papillomavirus DNA results.

Nine women with Class I (negative) smears (28%) had detectable human papillomavirus DNA in the samples of cervicovaginal cells. One patient had two smears taken 4 months apart; both were Class I and both lavage specimens contained human papillomavirus DNA. Smears from all 10 of these women were examined by a second cytopathologist, who confirmed that the samples were adequate and had no detectable abnormal cells.

To investigate the significance of the above findings (Table III), we examined the human papillomavirus DNA results and histopathologic findings in parallel biopsy specimens that were available in each group of patients with cervicovaginal cells either positive or negative for human papillomavirus DNA with negative Papanicolaou smears. None of the nine biopsy specimens from patients with negative cytologic results and negative cervicovaginal cell human papillomavirus DNA were positive for human papillomavirus DNA, whereas five of seven (71%) of the cervical biopsy specimens from patients with negative cytologic results and positive human papillomavirus DNA in the cervicovaginal cells were positive for human papillomavirus DNA. Moreover, histopathologic examination of biopsy specimens obtained simultaneously from patients with human papillomavirus DNA in the cervicovaginal cells but negative Papanicolaou smears demonstrated dysplasia in six of seven (86%). A retrospective review of the Papanicolaou smear results within a 1-year period revealed that six of nine (67%) patients who had negative cytologic results but positive human papillomavirus DNA in the cervicovaginal cells had had a Class III or IV smear in previous or subsequent specimens, whereas only four of 24 (17%) patients who had negative cytologic results and cervicovaginal cells negative for human papillomavirus DNA had had a Class III or IV smear in previous or subsequent specimens. Thus these negative Papanicolaou smears may represent faulty sampling (false negative) in at least 67% of the nine patients positive for human papillomavirus DNA in the cervicovaginal cells but with negative cytologic results.

Typing of human papillomaviruses in the 30 patients with human papillomaviruses DNA in the cervicovaginal cells was determined by restriction enzyme pattern and strength of hybridization with radiolabeled DNA probes from human papillomavirus types 6, 11, 16, and 18, and the results are shown in Table IV. At least five different types of human papillomaviruses were identified. Those samples that had neither strongest hybridization to a single human papillomavirus type nor characteristic restriction patterns were considered dis-

Table IV. Human papillomavirus types in exfoliated cervicovaginal cells correlated with Papanicolaou smear results

†One patient with human papillomavirus type 16 had two negative smears.

tinct from human papillomavirus types 6, 11, 16, and 18. In the 30 patients positive for viral DNA, human papillomavirus type 16 was detected in cervicovaginal cells from 12 (40%) patients, human papillomavirus type 18 in seven (23%), human papillomavirus type 11 in five (17%), human papillomavirus type 6 in two (7%), and "other" human papillomavirus types in five (17%). As illustrated previously (Fig. 1), one patient had both human papillomavirus type 11 and type 18 in the cervicovaginal cells. Human papillomavirus types 16, 18, and "other" were present in 14 of 17 (82%) women with Class III or Class IV Papanicolaou smears.

Comment

In this prospective study, we have collected exfoliated cervicovaginal cells by a painless, noninvasive cervicovaginal lavage technique in a group of women seen in a colposcopy clinic. We have detected human papillomavirus DNA in the exfoliated cells in 50% of such patients by restriction enzyme analysis and molecular hybridization. Since there are no other established methods to diagnose human papillomavirus infection, we have compared the analysis of human papillomavirus DNA in the lavaged samples with human papillomavirus DNA results in simultaneously performed colposcopically directed cervical biopsies. Detection of human papillomavirus DNA in cervicovaginal cells was correlated with the finding of human papillomavirus DNA in cervical biopsy samples, and, in fact, the human papillomavirus DNA was positive in the cervicovaginal cells even in cases in which the biopsy sample was negative. This probably results from the fact that the lavage technique samples exfoliated epithelial cells from the entire cervix, whereas the biopsy represents a focal sample. The detection of human papillomavirus DNA in cervicovaginal cells obtained by cervicovaginal lavage was indicative of a dysplastic cervical lesion in at least 95% of patients who had a colposcopically directed biopsy.

There is accumulating evidence from a variety of laboratories that human papillomavirus infection of the cervix may be one of the most important factors in the development of cervical dysplasia and carcinoma. However, the current standard method of cervical cancer screening is the Papanicolaou smear. Since the rate of false negative results obtained with analysis of a single Papanicolaou smear has been estimated to be between 10% and 50%,[10] the availability of another, more sensitive screening method is desirable to detect premalignant lesions of the cervix. Two recent reports identifying human papillomavirus infection in exfoliated cells from cervical swabs have identified human papillomavirus DNA by in situ filter hybridization (dot blot) in 83% (29 of 35) and 69% (49 of 71) of women with Class III or IV Papanicolaou smears.[24,25] In the present study, 94% (16 of 17) of patients with Class III or IV Papanicolaou smears had human papillomavirus DNA detected in cervicovaginal collected by lavage. It is noteworthy that the rate of detection of human papillomavirus DNA by the in situ filter hybridization method[16,17] in patients with Class I Papanicolaou smears was 11% (four of 36) and 2% (five of 229). In reviewing our experience, if the presence of human papillomavirus DNA is taken as an indication of a cervical lesion, the "false negative" cervical cytology rate for a single Class I Papanicolaou smear was 29%. In addition, those women with a Class I Papanicolaou smear and positive human papillomavirus DNA in the cervicovaginal cells had a very high incidence of another abnormal (Class III or IV) Papanicolaou smear in a 1-year time period and often had dysplasia on biopsy. The rate reported here of detection of human papillomavirus DNA in women with a single negative Papanicolaou smear is comparable to the rate of negative Papanicolaou smears obtained in women with an established dysplastic lesion either by the swab technique (51%) or by the swab-spatula technique (29%).[18]

In our study, the typing of different human papillomaviruses by restriction analysis and hybridization identified types 16 and 18 in 62% of patients with Class III and IV papillomavirus smears. In other studies, 65% (19 of 35) and 48% (27 of 56) had either human

papillomavirus type 16 and/or 18.[16, 17] Unfortunately, the use of dot blots as reported did not allow accurate typing of human papillomavirus DNA since the sample quantity may be limited and the identification is based on the strength of hybridization signal alone.[16, 17] An advantage of the lavage method reported here is the abundant quantity of exfoliated epithelial cells collected, which allows use of restriction analysis and separate hybridizations with multiple human papillomavirus probes to distinguish individual human papillomavirus types. By this method, it was clear that 17% (five of 30) of patients had a human papillomavirus type that was different from types 6, 11, 16, and 18. We detected one mixed infection (3%) with human papillomavirus types 11 and 18 (Fig. 1). Other groups have reported mixed infection in 7% (two of 29) and 14% (10 of 71) of patients.[16, 17] Since the biologic behavior and natural history are unknown for individual types of human papillomaviruses, we believe it is important to identify and study the clinical course of infection with each human papillomavirus type separately.

The results of the present study support the hypothesis that human papillomavirus infection of the cervix and associated dysplastic epithelial lesions may be part of the natural history of cervical cancer. The clinical significance of lavage screening with the finding of a specific type of human papillomavirus DNA in exfoliated cervical cells is the opportunity to identify associated dysplastic lesions by colposcopy that are amenable to therapy. A coordinated investigation of these findings is being undertaken to elucidate the propensity of lesions containing specific human papillomavirus types to progress. Although human papillomavirus types 16 and 18 are known to be present in the majority of cervical cancers,[2, 3] it is not known at present what percentage of cervical infections with these viruses will progress to malignancy. Moreover, the presence of acute versus persistent viral infection may significantly alter the risk of developing cervical cancer, similar to the observation that persistent infection with hepatitis B virus, and not simply a limited previous acute infection, is the predominant risk factor in developing hepatocellular carcinoma.[19] What is clear from our study and those of others is that human papillomavirus infection of the cervix is commonly found in women with abnormal Papanicolaou smears and in women who have dysplastic lesions, even in the presence of normal Papanicolaou smears. Although it is not known what the prevalence rate of human papillomavirus infection detected by DNA hybridization may be in a random screening of defined population groups, our data suggest a very high correlation between the findings of human papillomavirus DNA in cervicovaginal cells and an associated dysplastic cervical lesion. The detection of human papillomavirus DNA by the methods described here offers an objective assessment of human papillomavirus infection and can serve to identify those women who should be carefully evaluated for a dysplastic lesion of the cervix. The advantages of the method described here over the Papanicolaou smear as a screening test for precancerous lesions include: (1) greater sensitivity of detection of dysplastic lesions and (2) potential for greater prognostic information from human papillomavirus type than from morphologic results alone. Thus collection of exfoliated cells for human papillomavirus DNA detection by the lavage method offers a simple, noninvasive technique that can be performed in the gynecologist's office in conjunction with a molecular biology laboratory. Its usefulness as a generalized screening method and as a means of longitudinal evaluation is currently under study.

We thank Dr. David A. Shafritz for continuous advice and support throughout the project; Annette Dwyer, R.N., and Ana Martinez for their assistance in recruiting and orienting patients; Anna Caponigro for preparation of the manuscript; and Robert Hagan for cytologic evaluation of patient material.

Toxic shock syndrome, contraceptive methods, and vaginitis

Stephan F. Lanes, Ph.D., Charles Poole, M.P.H., Nancy A. Dreyer, Ph.D., and Lee L. Lanza, M.P.H.

Chestnut Hill, Massachusetts

To elucidate further the etiology of toxic shock syndrome, we assessed the effects of certain contraceptive methods and recent history of vaginal infection on the incidence of toxic shock syndrome, with confounding effects of other risk factors controlled. We found a strong but imprecise positive association between toxic shock syndrome and tubal ligation (rate ratio = 7.9, 90% confidence interval 1.4 to 42.7). We also observed a negative association with oral contraceptives (rate ratio = 0.49, 90% confidence interval 0.22 to 1.1) and a positive association with a recent history of vaginitis (rate ratio = 2.1, 90% confidence interval 1.2 to 3.9). (Am J Obstet Gynecol 1986;154:989-91.)

Key words: Toxic shock syndrome, contraception, vaginitis

Tampon use in general and certain characteristics of tampons, such as brand and absorbency, have been reported to be important determinants of the incidence of toxic shock syndrome.[1] For the many women who continue to use tampons, however, little is known about preventive measures for reducing the risk of toxic shock syndrome. An apparent reduction in the incidence of toxic shock syndrome among users of oral contraceptives was observed[2] in the crude data from two early studies.[3, 4] The same inverse association is present in the crude data from two subsequent studies,[5, 6] as is a positive association with a recent history of vaginitis. The purpose of this analysis is to evaluate further the possible effects of specific contraceptive methods and vaginitis on the incidence of toxic shock syndrome by controlling the confounding effects of recognized risk factors.

Methods

We obtained a computer tape of data from the Tri-State study,[6] the largest study of toxic shock syndrome conducted to date. To verify the data, we reproduced the published results.[6] The Tri-State study included all 76 nonfatal cases of toxic shock syndrome occurring in women during a menstrual period that were reported to the Iowa, Minnesota, and Wisconsin state health departments between October 1, 1979, and September 19, 1980. For each case, two controls were selected and matched to the case by date of birth and neighborhood of residence. All controls were required to have experienced a menstrual period within 2 months of onset of toxic shock syndrome in the matched case. Other details of the design and conduct of the study have been published previously.[6]

The present analysis was restricted to the 75 cases and 123 controls who were menstruating and using tampons at the time of toxic shock syndrome onset. Information about menstruation, tampons, and contraceptive methods relates to the time of the index menstrual period, which is defined for cases as the menstrual period during which toxic shock syndrome occurred. For controls, it is defined as the menstrual period closest in time to the index menstrual period of the matched case. We estimated effects of seven contraceptive methods reported by the women in this study: condom, diaphragm, foam, intrauterine contraceptive device, oral contraceptives, tubal ligation, and vasectomy. The unexposed group comprised women

Vasectomy	3	4	1.2	1.2	0.29-4.6*
Vaginitis	21	19	2.1	2.1	1.2-3.9*

*Confidence interval reported for crude estimate.

who reported using no contraception (50 cases, 79 controls). For the analysis of vaginitis, comparison was made to women reporting no history of vaginitis in the past year (54 cases, 104 controls).

A summary rate ratio (RR) estimate for each contraceptive method and for vaginitis across categories of potentially confounding variables was obtained by standardizing the RR according to the distribution of each confounding variable among the controls in the high-risk stratum of the risk factor being evaluated.[7] To control for the matching variables, uniform RR estimates were computed by the method of maximum likelihood.[8] We considered as potentially confounding variables age, neighborhood, tampon brand (Rely brand/other brands), tampon fluid capacity, vaginitis (for analysis of contraceptive methods), and the specific contraceptive methods (for analysis of vaginitis). A comparison of the standardized RR to the crude (unstandardized) RR indicates the degree of bias attributable to the confounding variable.[7] When adjustment was indicated we reported the standardized estimate; otherwise we reported the crude estimate of RR. Approximate confidence intervals for the standardized RR were calculated according to a Taylor series approximation, and for crude estimates of RR we calculated exact confidence intervals.[9] We evaluated the degree of random error in the estimates of RR by examining the widths of the confidence intervals.[10]

Results

Estimates of RR for each type of contraceptive method and vaginitis are presented in Table I. Tubal ligation is associated with a marked increase in the incidence of toxic shock syndrome (RR = 7.9). The confidence interval is wide, indicating that the estimate of RR is imprecise, but the position of the interval clearly denotes a positive association that is likely to be strong.

The data show a negative association for oral contraceptive use (RR = 0.49). The confidence limits indicate that, with respect to random error, these data provide moderately strong evidence of a reduction in the incidence of toxic shock syndrome among oral contraceptive users.

A history of vaginitis in the past year is associated with a doubling of the incidence rate of toxic shock syndrome (RR = 2.1). The confidence limits indicate that the estimate is sufficiently precise to provide considerable evidence of a positive association.

The estimates of RR for use of condom, diaphragm, foam, intrauterine contraceptive device, and vasectomy are very imprecise, and therefore the data provide only scant information about the relation of these contraceptive methods to the incidence of toxic shock syndrome.

Comment

The strong association between toxic shock syndrome and tubal ligation has not been reported previously. The association is based on only three exposed cases, so the explanation for this result is unclear; however, a causal interpretation would have important implications for the increasing number of young women choosing this method of contraception.[11] Of the cases reporting a tubal ligation, all reported having had the procedure at least 1 year before the onset of toxic shock syndrome, thereby precluding an acute effect of the operation. Previous analyses have combined tubal ligation with other contraceptive methods, thus preventing a comparison with the results we report.

A negative association between oral contraceptive use and toxic shock syndrome has been reported.[2] Our analysis demonstrates that the apparent reduction in the toxic shock syndrome incidence rate among oral contraceptive users cannot be explained by confounding effects of recognized risk factors. A protective effect of oral contraceptives against pelvic inflammatory dis-

ease has been suggested,[12] and it is possible that oral contraceptives protect against several kinds of vaginal infection.[2]

An approximate doubling of the incidence rate of toxic shock syndrome is observed for women reporting a history of vaginitis in the previous year. Crude data from one previous study show a weak positive association for this exposure (RR = 1.4).[5] Recurrent toxic shock syndrome has been reported among menstruating women[3]; women reporting a history of vaginitis in the past year may have experienced prediagnostic symptoms of toxic shock syndrome. An alternative explanation is that toxic shock syndrome shares etiologic factors with other forms of vaginal infection.

The range of associations we report for various types of contraceptive methods and for vaginitis makes it difficult to attribute these results to a common bias. The association for oral contraceptives is in the opposite direction from the association for tubal ligation. In order for both of these results to be explained by bias, at least two sources of bias would have to be proposed. Each would have to be specific to the particular method and unrelated to contraceptive use or to sexual activity in general. Yet another explanation would be required for the vaginitis association seen in these data.

This analysis provides evidence about possible risk factors for toxic shock syndrome that have received little attention thus far. Although more evidence is needed before the relations reported here can be clearly understood, the results suggest that the etiology of toxic shock syndrome may involve a variety of gynecologic factors in addition to menstruation and tampon use.

We are grateful to Dr. Kenneth J. Rothman for providing the procedure used to calculate approximate confidence intervals for standardized estimates.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Necessity of endocervical curettage in colposcopy

Karan R. Moseley, M.D., Tung V. Dinh, M.D., Edward V. Hannigan, M.D., E. A. Dillard, Jr., M.D., and Roger B. Yandell, M.D.

Galveston, Texas

The use of endocervical curettage was evaluated in 200 patients undergoing colposcopy, biopsy, endocervical curettage, and conization. It is suggested that endocervical curettage be performed only in cases of satisfactory colposcopy, since patients with unsatisfactory colposcopy should undergo conization. (AM J OBSTET GYNECOL 1986;154:992-5.)

Key words: Endocervical curettage, colposcopy, biopsy, conization

With the use of colposcopy to evaluate cervical lesions, the management of women with abnormal Papanicolaou smears has become more individualized, with fewer indications for diagnostic conization. To improve the diagnostic accuracy before outpatient treatment of cervical intraepithelial neoplasia, Townsend and Richart[1] have suggested that endocervical curettage be a standard part of a colposcopic examination. This suggestion has not been accepted by all authors.[2-7]

Our present study is undertaken to determine the utility of endocervical curettage in evaluating patients who have both satisfactory and unsatisfactory colposcopic examinations.

Material and methods

Between 1981 and 1983, a total of 824 patients were seen in the dysplasia clinic of the University of Texas Medical Branch at Galveston; 263 of these patients (32%) underwent conization of the cervix. Data concerning cervical biopsies, endocervical curettage, and conization of the first 200 patients were included in this study. No patient was pregnant at the time of evaluation. Cervical dysplasia was classified according to Richart's scheme[8]: grade 1, 2, or 3 cervical intraepithelial neoplasia. Microinvasion was defined as stromal invasion of 3 mm or less below the basement membrane of the epithelium from which it arose, without vascular or lymphatic involvement or confluence of neoplastic tongues. When more than one specimen was collected, the most severe diagnosis was reported. Cervical biopsies and cone specimens were categorized according to the degree of dysplasia. The findings of endocervical curettage were classified as positive if any dysplastic cells were noted on the curettage specimen.

Results

Of 200 patients undergoing conization, 113 (57%) had unsatisfactory and 87 (43%) had satisfactory colposcopic examinations.

The degree of cervical intraepithelial neoplasia on cervical biopsy specimens was compared to the positive or negative results of the endocervical curettage. Among 113 patients with unsatisfactory colposcopy (Table I), 62 (55%) had a negative finding on endocervical curettage and 51 (45%) had a positive finding. Three patients (3%) with negative biopsy results had a positive finding on endocervical curettage. Among 87 patients with satisfactory colposcopy who were undergoing conization for other reasons (positive endocervical curettage specimen, wide geographic disease, Papanicolaou smear, or biopsy suggestive of invasion) (Table II), 18 (21%) had a negative endocervical curettage finding and 69 (79%) had a positive finding. Eleven patients (13%) who had negative biopsy results had a positive endocervical curettage finding.

The degree of cervical intraepithelial neoplasia on conization specimens was compared to the positivity and negativity of the endocervical curettage specimens. Among 62 patients with an unsatisfactory colposcopy and a negative endocervical curettage finding (Table III), 50 (81%) had a dysplasia of the cervix on conization specimens ranging from grade 1 to grade 3 cervical intraepithelial neoplasia. None had invasive carcinoma. Among 51 patients with an unsatisfactory colposcopy and a positive endocervical curettage specimen (Table III), 49 (96%) had dysplasia of the cervix on conization specimens ranging from grade 1 cervical intraepithelial neoplasia to invasive carcinoma. It is to be noted that 30 patients had grade 3 cervical intraepithelial neoplasia and six had microinvasive disease. Among 18 patients with a satisfactory colposcopy and a negative en-

docervical curettage finding (Table IV), 18 (100%) had dysplasia of the cervix on conization specimens ranging from grade 1 cervical intraepithelial neoplasia to invasive carcinoma. Among 69 patients with satisfactory colposcopy and positive endocervical curettage results (Table IV), the final diagnosis on conization specimens was grade 1 cervical intraepithelial neoplasia to invasive disease in 59 patients (85%). One patient had microinvasion and one had invasive disease.

Ten cases of microinvasive carcinoma and one case of invasive carcinoma were diagnosed among 200 patients undergoing conization (5.5%). It is of interest that the endocervical curettage had negative results for dysplasia and that the colposcopy was satisfactory in three cases. The reasons for conization were a wide geographic lesion associated with a biopsy revealing grade 3 cervical intraepithelial neoplasia in two cases and a cervical biopsy suggesting invasive disease in one case.

Comment

The endocervical curettage, which was a required step in this study, has been advocated by many authors. Townsend et al.[9, 10] recommended endocervical curettage with all colposcopic examinations and subsequent conization in the presence of dysplastic disease in the canal. In studying patients with invasive carcinoma missed after colposcopic examination, they stated that the most common omissions were the failure to perform an endocervical curettage and the failure to take an adequate number of biopsy specimens. Shingleton et al.[11] used endocervical curettage in 603 patients. They emphasized that curettings are more reliable than endocervical smears for the diagnosis of cervical neoplasia and proceeded to definitive therapy, either cryotherapy or hysterectomy, without prior conization if the curettings were no worse than moderately dysplastic. They have found that the cervical biopsy diagnosis was the same as the final pathologic diagnosis in 86% of cases with negative endocervical curettage findings but in only 68% of cases with positive endocervical curettage findings. Kelley et al.[12] reviewed 250 patients who had conization or hysterectomy following colposcopic biopsies and endocervical curettage. Biopsy and endocervical curettage diagnoses corresponded

*One invasive carcinoma.

with the final diagnosis in 92% of cases. No invasive cancer was missed. Hatch et al.[13] also advocated the use of endocervical curettage in all cases. In 125 patients with inadequate colposcopy, nine patients had invasive cancer and five patients, microinvasive disease. All of these cases were associated with a positive finding on endocervical curettage. The authors concluded that the endocervical curettage gave valuable information for outpatient treatment and eliminated the need for conization in 76% of patients after unsatisfactory examinations.

Conversely, other authors do not perform an endocervical curettage, or they use it only in cases of unsatisfactory colposcopy. Talebian et al.,[2] using only colposcopically directed biopsies, found 100% accuracy in cases of satisfactory colposcopy in 114 patients undergoing conization or hysterectomy. On the contrary, among 54 patients with unsatisfactory colposcopic examination, 56% showed more advanced disease on conization. Swan[3] used colposcopically guided biopsies without endocervical curettage in 763 patients and reported a high degree of accuracy (98.4%) comparable to other reports. Javaheri and Fejgin,[4] in a series of 930 patients, concluded that omission of endocervical curettage in patients with satisfactory colposcopy did not reduce the accuracy of the diagnosis. He advised, however, the performance of an endocervical curettage in all patients with unsatisfactory colposcopy. After adequate colposcopy an exact diagnosis was reached in 76.5% of cases; after inadequate colposcopy a more advanced lesion was detected in over 50% of cases. Urcuyo et al.[5] noted that among patients with adequate colposcopy, 8.6% had positive endocervical curettings, but a more severe lesion was never found in comparison with cervical biopsies, conization, or hysterectomy. In patients with unsatisfactory colposcopy, 57.3% had positive endocervical curettings, and in two patients the curettings showed invasive cancer. He concluded that endocervical curettage was of little value in cases of adequate colposcopy results but was indicated when results were unsatisfactory, since a frank invasive carcinoma may be diagnosed and conization avoided.

On the other hand, Rochelson and Krumholz[6] withheld endocervical curettage in patients with unsatisfactory colposcopic examinations because it increases patient discomfort and because the patients were to undergo conization subsequently. Drescher et al.,[7] in a review of 540 patients, reported positive endocervical curettage findings in 17.9% of patients with satisfactory colposcopy and in 48.7% of patients with unsatisfactory colposcopy. In cases of both satisfactory and unsatisfactory examinations, the diagnosis on endocervical curettage was more significant than that with the cervical biopsies in 3.8% and 21.1% of cases, respectively. They advocated that endocervical curettage be done in all patients except those for whom cone biopsy is planned.

Our experience seems to agree with the findings of Rochelson and Krumholz[6] and of Drescher et al.[7] Positive endocervical curettage results were the most frequent reason (58%) for conization in our patient pop-

ulation. The endocervical curettage results were positive in 45% (51 of 113) of patients with unsatisfactory colposcopy and 10.6% (69 of 648) of patients with satisfactory colposcopy.

The data from this study can be used to answer the question, does endocervical curettage add anything to an adequate colposcopic examination with colposcopically directed biopsies? The data support an affirmative answer because 79% of patients had positive results for dysplasia on endocervical curettage. Among those patients, 13% had normal cervical biopsies (Table II). In addition, 85% of patients undergoing conization had dysplasia of the cervix ranging from grade 1 cervical intraepithelial neoplasia to invasive disease. One case of invasive carcinoma and one case of microinvasive carcinoma would have been missed had the endocervical curettage and subsequent conization not been performed (Table IV). The positivity of endocervical curettage findings is one of the reasons for conization in these patients with satisfactory colposcopic examinations.

The second question concerns the utility of endocervical curettage after an unsatisfactory colposcopic examination. Although 45% of patients had positive results for dysplasia on endocervical curettage, among which two cases showed possible invasion by biopsy (Table I), those patients would not have avoided conization because of the unsatisfactory examinations. After unsatisfactory colposcopy, an endocervical curettage adds nothing to the diagnosis. Even the diagnosis of frank invasive disease cannot be made affirmatively on endocervical curettings because of the scant stroma. Furthermore, a previous endocervical curettage hampers the pathologic interpretation of the cone specimen if conization is performed soon after endocervical curettage. For these reasons, we believe the endocervical curettage can be omitted in all cases after unsatisfactory colposcopy, since conization is indicated (Fig. 1).

In all cases, however, correlation between cytologic findings, colposcopic findings, biopsy results, and endocervical curettage results should be strictly maintained before outpatient treatment is given or surgery is performed.[14]

Physiologic changes in pregnant women and their fetuses during jet air travel

Renate Huch, M.D., Hans Baumann, M.D., Falk Fallenstein, M.Sc., Karl T. M. Schneider, M.D., Fridolin Holdener, M.D., and Albert Huch, M.D.

Zurich, Switzerland

The physiologic reactions of pregnant women and their fetuses were studied during routine commercial flights. Ten healthy pregnant women (32 to 38 weeks of gestation) each undertook two flights. Maternal respiratory and heart rates, transcutaneous Po_2 and Pco_2, blood pressure, uterine activity, and fetal beat-to-beat heart rate variability were continuously monitored. During these flights, maternal heart rate and blood pressure increased, and Po_2 decreased significantly while Pco_2 remained unchanged. Respiratory rate showed a short increase during takeoff and landing but remained unchanged during the rest of the flight. Mean fetal heart rate was within normal limits during the whole flight. No bradycardia, prolonged tachycardia, or significant loss of heart rate variability was observed. This study indicates no hazards of commercial flights to the mother and the fetus in uncomplicated pregnancies. (Am J Obstet Gynecol 1986;154:996-1000.)

Key words: Pregnancy, fetus, altitude, hypoxia, maternal anxiety, jet air travel

Obstetricians vary in their advice to pregnant women regarding air travel. These divergent opinions result partly from lack of knowledge of the physiologic adaptations of the maternal-fetal unit during flight. There are at least two significant questions that require investigation: Can the emotional stress of the mother during flight lead to reduced uterine circulation? What is the effect on the mother and the fetus of short-term altitude exposure?

Modern aircraft maintain a cabin pressure corresponding to an altitude between that of the airport and 2500 m (8200 feet). Consequently, the oxygen partial pressure in the cabin air is reduced. Both theoretical calculations and measurements in healthy adults give arterial Po_2 values between 60 and 70 mm Hg under the conditions occurring during commercial flights.[1] The effect on the fetus of this reduction of maternal Po_2 is unknown. Theoretical discussions of this question by Cameron,[2] Parer,[3] and Scholten[4] have concluded that given normal placental function, the fetus should be unaffected. However, there are no studies under simulated or actual flying conditions to support this conclusion. To help clarify the effect of air travel on pregnant women and their fetuses, we studied mothers and fetuses during commercial flights.

Material and methods

The study was performed on Swissair flights between Zurich, Switzerland, and Amsterdam, The Netherlands, or Zurich, Switzerland, and Copenhagen, Denmark. The aircraft used was a DC 9 and the flight time was 1 to 1½ hours. Measurements were repeated on each mother during the return flight. Approval for this study was obtained from the Ethical Committee of the University. Table I gives details of the pregnant volunteers and the variables monitored.

Each flight was divided into five phases: takeoff, climbing, cruising, descent, and landing. As seen in Fig. 1, the data were analyzed with respect to the different phases of the flight. Within each phase mean values of 6-minute periods were calculated. The method of Fallenstein et al.[5] was used to analyze fetal heart rate variability. Paired *t* tests were used for statistical comparisons.

Results

No complications occurred during flight and subsequently all the women were delivered of healthy infants.

Flight data. The cabin pressure at maximal altitude averaged 586 (555 to 597) mm Hg corresponding to a simulated altitude of 2395 (2635 to 1900) m or 7855 (8642 to 6227) feet. This level of cabin pressure was reached at an average of 15 minutes after takeoff.

The mother

Transcutaneous blood gases. As expected, maternal transcutaneous Po_2 fell during flight (Fig. 1) and paralleled the decrease in cabin pressure. The mean fall in transcutaneous Po_2 at peak altitude was 25%.

Table I. Characteristics of the women studied and the variables measured

Pregnant volunteers	
Total number	10
Mean age (yr)	28
Primiparous	7
Smoker	2
Length of gestation (wk)	32-38
Parameter monitored *(continuously and noninvasively)*	Instrument used
Maternal transcutaneous P_{O_2}	Self-developed equipment
Maternal transcutaneous P_{CO_2}	
Maternal respiratory rate	Cardiorespirograph, Hellige, Freiburg, Federal Republic of Germany
Maternal heart rate (from electrocardiogram)	
Maternal blood pressure, systolic	Dinamap, Applied Medical Research, Tampa, Florida
Maternal blood pressure, diastolic	
Maternal uterine pressure (external)	Cardiotocograph HP 8040A, Hewlett-Packard, Böbligen, Federal Republic of Germany
Fetal heart rate (ultrasound Doppler)	
Cabin pressure (electronic barometer)	Self-developed equipment

No change, such as a fall due to hyperventilation, was seen in transcutaneous P_{CO_2}, which was constant in all patients throughout the flights.

Respiratory rates. Mean maternal respiratory rates were between 20 and 26 breaths per minute in the various flight phases. Before and during takeoff there was some increase in respiratory rate, but respiratory rate then decreased and remained stable in subsequent phases of the flight. In one woman ventilation briefly increased to a rate of 70 breaths per minute during landing of the airplane.

Heart rate. The results of the maternal heart rate recordings are seen in Fig. 1. Baseline heart rate was 86 bpm and increased gradually during the flight. In addition a peak was seen during takeoff and a second peak was reached at maximal altitude. This level was significantly higher than the initial peak during takeoff ($p < 0.001$). Another small rise was noted during landing. Individual increases up to 120 bpm were noted.

Five of the women showed cyclic changes in heart rate as illustrated in Fig. 2. They had an amplitude of about 20 bpm and appeared with intervals of 2 to 3 minutes. The return to the initial baseline heart rate was always associated with a contraction (see *arrows* in Fig. 2).

Blood pressure. Mean systolic and diastolic blood pressures, respectively, ranged between 116 and 124 mm Hg and between 66 and 74 mm Hg. The diastolic pressure fell during ascent ($p < 0.001$) but both values were

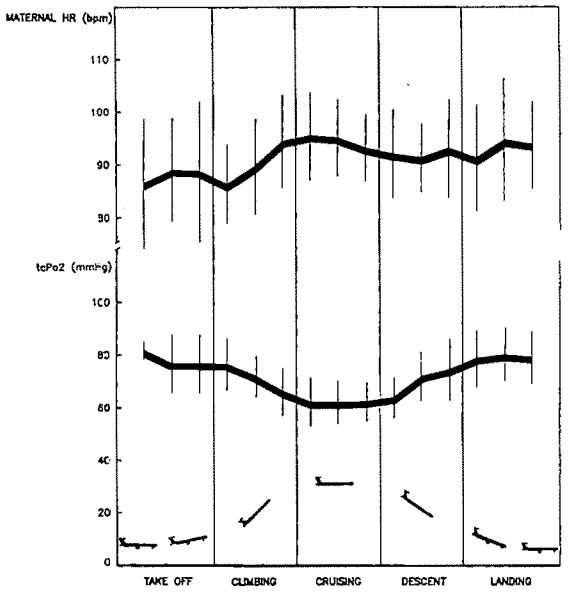

Fig. 1. Mean (±SD) maternal (10 women, 20 flights) heart rate and transcutaneous P_{O_2} *($tcPo_2$)* values during the various flight phases.

increased over baseline at peak altitude. Upon landing, blood pressure returned to preflight levels.

Uterine activity. The regular contractions discussed in connection with the cyclic heart rate changes were not felt by the mother. The frequency of sporadic contractions was consistent with the time of gestation.

The fetus. Fig. 3 illustrates the changes in the mean baseline fetal heart rate. There was a small but statistically significant ($p < 0.02$) increase during takeoff and during approach to landing ($p < 0.05$). In all flight phases, however, mean baseline fetal heart rate was within normal limits. The mean amplitude of the long-term variability of the fetal heart rates can be seen in the lower part of Fig. 3. There is no indication of reduced fetal heart rate variability.

Individual heart rate patterns in seven fetuses showed no significant change related to particular flight phases. Only three times during takeoff and ascent and once at cruising altitude (three fetuses) were marked accelerations (three of short duration and one of 8 minutes) noted.

Comment

Man cannot tolerate the low oxygen pressure where ordinary jet aircraft cruise, that is, 9000 to 12,000 m (30,000 to 40,000 feet) and 15,000 to 18,000 m (50,000 to 80,000 feet) for the Concorde, so all commercial jet airlines are pressurized. To reduce weight and cost, compression of incoming air is limited so that the resulting oxygen tension is equivalent to that at 1500 to 2450 m (about 5000 to 8000 feet). Many women live permanently at these altitudes, for example, in Switzer-

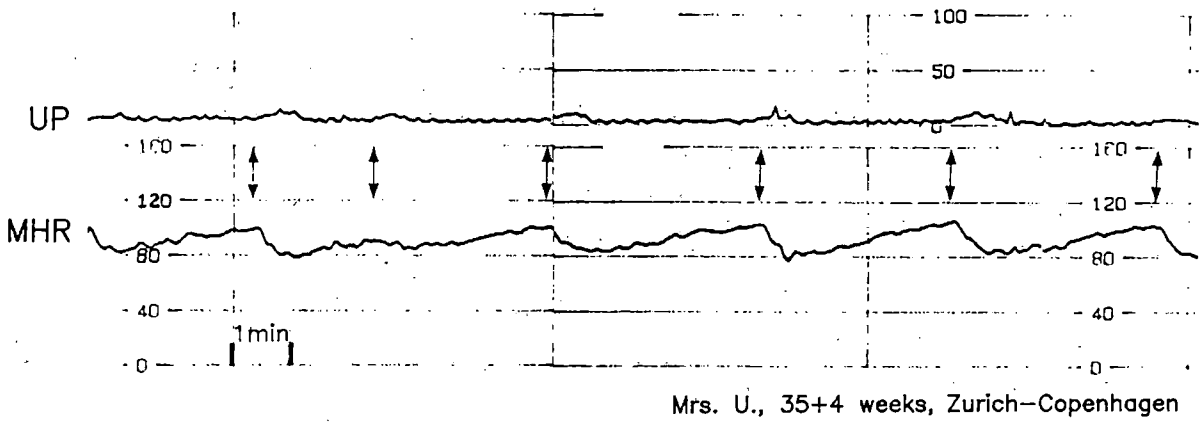

Fig. 2. Recordings of maternal heart rate *(MHR)* and external uterine pressure *(UP)* in a pregnant woman during flight showing the relationship between slight uterine contractions and maternal heart rate fluctuations *(arrows)*.

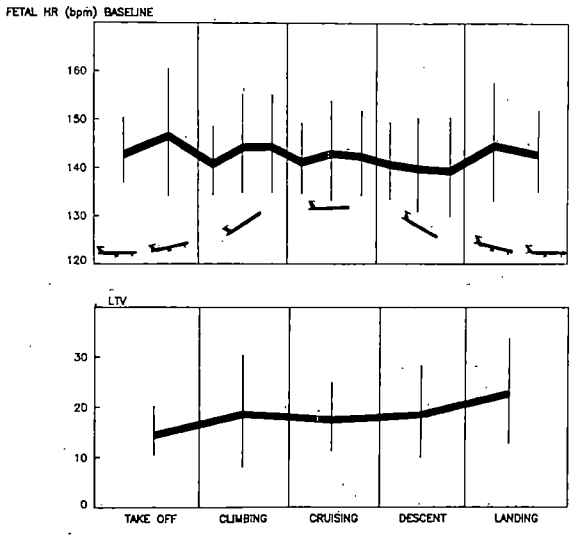

Fig. 3. Mean (±SD) fetal (10 fetuses, 20 flights) beat-to-beat heart rate baseline and long-term variability *(LTV)* in the various flight phases.

land or North and South America, and there is no evidence of any adverse consequence for pregnancy. However, at 3000 m and above, the evidence for a negative influence of the resulting hypoxia on reproduction is unanimous. Systematic studies (reviewed by Huch[6]) controlling for the multifactorial influences of race, low socioeconomic status, cold, and radiation have demonstrated the adverse role of reduced oxygen pressure in fetal outcome. However, there are several mechanisms of mother and fetus to adjust to life at high altitude but because of lack of time to adapt to short-term exposure to conditions in flight equivalent to altitudes of about 2500 m, some negative influence on the fetus might be anticipated even at these heights.

Under normal flight conditions, the lowest oxygen partial pressure to which passengers should be exposed is about 110 mm Hg. This corresponds to an oxygen concentration of 15% at sea level and represents a reduction of about 28% from normal. This agrees with our findings that maternal transcutaneous Po_2 fell by a mean of 25% from the initial value in Zurich (altitude 440 m). Wulf[7] studied pregnant women inhaling a gas mixture containing 15% oxygen. The mean arterial Po_2 value in 63 women was 65 mm Hg and similar results have been obtained in non-pregnant adults.[1, 8]

The decrease in Po_2 in our patients occurred without a significant change in respiratory rate. The small increases in respiratory rate noted at takeoff and landing were felt to be emotionally induced by these phases of the flight. No direct measurement of the tidal volume was performed, but the stable transcutaneous Pco_2 values coupled with a stable respiratory rate indicate no major change in tidal volume. The results clearly show that flying does not augment the already existing state of hyperventilation in pregnant women.[9, 10]

Pregnant women as well as nonpregnant adults[8, 11, 12] react to a reduction in inspired oxygen content with an increase in heart rate and systolic pressure. In our study the increase in maternal heart rate paralleled the drop in transcutaneous Po_2. Additional factors may also be involved as the maternal heart rate did not return completely to baseline at the end of the flight. It may for instance be relevant that the mothers and the equipment were observed and discussed by the other passengers.

Because of the instrumentation the mothers were partially immobilized in the sitting position during the flights. This positioning may explain the cyclic heart rate accelerations noted in five of the 10 women studied (Fig. 2). We previously described in late pregnancy a similar reaction with standing.[13] Pronounced phasic maternal heart rate accelerations occur in order to compensate for a reduced venous return from the lower

extremities. During standing venous return is impaired because of compression by the uterus, analogous to the vena cava syndrome in supine woman in late pregnancy. We have seen that during standing venous return improves phasically with uterine contractions. Such changes may also be associated to a lesser degree with sitting. Whether this reaction is detrimental to the fetus is presently not known, but it may be wise to encourage pregnant passengers to move about more often than they might otherwise do, especially on long-distance flights where one might anticipate an aggravation of any problem related to immobilization. Besides a lower oxygen tension there are other hazards that may be a function of flight duration, such as tobacco smoke, ozone, and cosmic rays. Whether these additional factors have a negative influence on mother and fetus during flight is not known. On the other hand, the effect of maternal hypoxemia that we have been discussing might be even less in transatlantic flights where cabin pressures tend to be higher than on the short-distance flights that we studied.

Fetal heart rate in flight was analyzed for evidence of fetal distress according to the usual antepartum or intrapartum criteria. In the present study the heart rate recordings obtained in all fetuses were of good technical quality and could be reliably assessed for the presence or absence of distress. The data do not reveal any convincing indications that the fetuses had to compensate for reduced blood flow secondary to maternal anxiety or maternal hypoxia induced by altitude. Notable fetal heart rate accelerations occurred only three times in the takeoff and initial climbing phases. As they were not paralleled by maternal heart rate accelerations, we believe that they reflect fetal arousal reactions resulting from vibration and accelerations during takeoff rather than changes secondary to maternal stress. With an exception of an 8-minute acceleration period to about 180 bpm in one fetus at cruising altitude who on the return flight did not show any heart rate abnormality, heart rate behavior of the fetuses was not suspicious for hypoxia at any instant during 30 hours of fetal monitoring during flight.

The results of our study during flight show moderate but significant cardiopulmonary changes in mothers but no significant fetal reactions. We are convinced that for normal uncomplicated pregnancies, flying as a passenger in modern aircraft can be recommended without restrictions. Late pregnancies were chosen for study because physiologic changes are most marked at this time and fetal monitoring is technically easier. As we are not aware of any data showing improved adaptation to stress and hypoxemia with increasing gestational age, we believe we can extrapolate our findings in late pregnancy to include the entire gestational period. However, an aircraft is certainly not a suitable place to give birth and it is obvious that airline restrictions on the use of air transportation during the final weeks of pregnancy should be observed whenever possible.

The situation of the pregnant stewardess may be different because here, in addition to the altitude exposure, the effect of physical work on mother and fetus needs to be considered.[14] Yoshioka et al.[15] studied nonpregnant flight attendants on the ground and during flights (cabin pressures corresponding to 1500 m (4920 feet) in DC 10 and 747 aircraft) and found their work to be quite strenuous. Heart rate increases for the same work were always more pronounced at altitude compared to those at ground level. Even simple walking in the aisle of the cabin at several degrees of inclination produced a significant rise in heart rate. Our analogous studies in the Swiss mountains (Laax, at 2200 m, 7200 feet) with pregnant volunteers who exercised for 3 minutes on a bicycle at 25 W resulted in maternal heart rate changes of a similar order of magnitude. With one exception, however, the fetuses did not display any signs of distress. This exception occurred in a pregnant woman who smoked and whose fetus exhibited a brief period of bradycardia after exercise. This stresses the need for careful examination and evaluation of additional risk factors that might impair fetal capacity to adjust to reduced uterine blood flow and maternal hypoxemia.

In summary, flying in modern commercial aircraft should not be considered harmful to the pregnant woman and her fetus if additional risk factors are excluded.

We acknowledge the cooperation of the 10 pregnant women without whom this study would not have been possible.

Moderate recreational running is associated with lowered salivary progesterone profiles in women

Peter T. Ellison, Ph.D., and Catherine Lager, B.A.
Cambridge, Massachusetts

Salivary progesterone profiles were studied in a group of recreational women runners (average 12.5 miles per week) and nonexercising control subjects. Although no differences were observed in the average cycle lengths of the two groups, luteal progesterone levels, both peak and average, were found to be significantly lower in the runners. A salivary progesterone level two standard deviations above the follicular phase average was used to discriminate luteal activity with 95% confidence. Runners averaged fewer days with sample values two standard deviations above this level and a shorter average interval between first and last samples observed above this level. However, no evidence was found of a delayed luteal progesterone rise among the runners. These results suggest that even moderate amounts of aerobic exercise may have effects on female reproductive function which would not be suspected from menstrual patterns alone. (AM J OBSTET GYNECOL 1986;154:1000-3.)

Key words: Progesterone, luteal phase, exercise, menstrual cycle, saliva

Numerous recent reports have provided evidence of a suppression of reproductive function in women athletes. Studies of menstrual histories have shown an increased incidence of oligomenorrhea and amenorrhea among competitive runners[1, 2] and swimmers[3] and among ballet performers,[4] relative to age-matched controls. Studies of acute hormonal responses have shown that exercise leads to increased levels of circulating steroids in women, but not always of gonadotropins.[5, 6] In addition, elevated concentrations of hormones with antireproductive properties have been observed in women following exercise.[3, 6, 7]

Chronic hormonal responses to regular exercise are less well documented. Shangold et al.[8] report a significant suppression of luteal phase progesterone secretion in a single runner and a negative correlation in the same subject between length of the luteal phase (determined by cervical mucus changes) and weekly training mileage. It is noteworthy that no differences in overall cycle length were observed between control and training cycles in this subject. Bonen et al.[9] compared hormone profiles of four elite teenage swimmers for a single month with age-matched controls and fertile adults. Luteal progesterone was also lowered and luteal phase length shortened in this group compared to both control groups. Most recently Bullen et al.[10] reported that increased incidence of menstrual irregularities, low progesterone levels, and absent luteinizing hormone peaks could be induced by subjecting volunteers to a 2-month exercise regimen beginning with running 28 miles/week, progressing to 70 miles/week, and including 3½ hr/day of additional aerobic exercise.

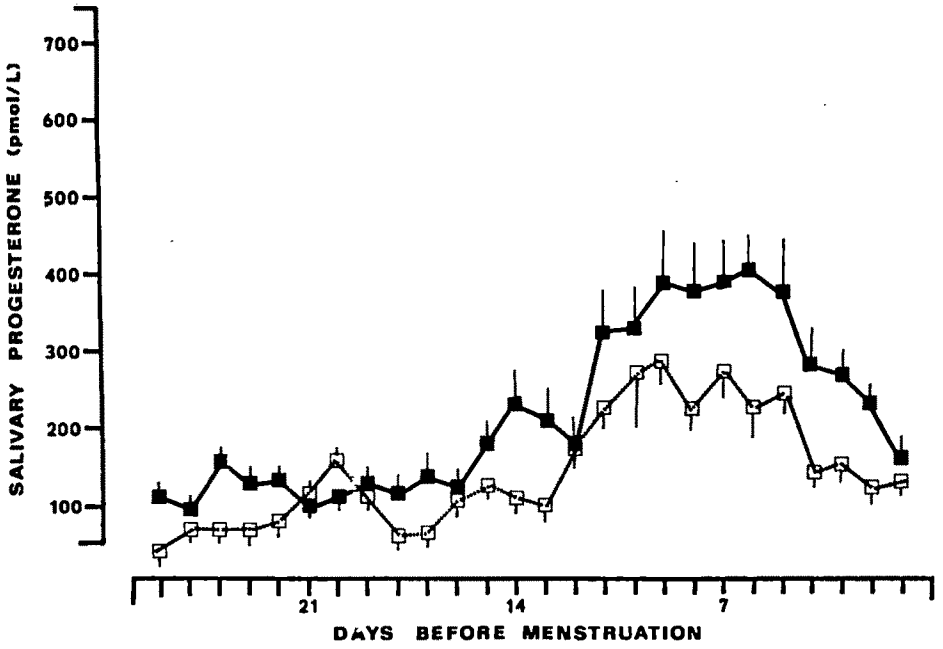

Fig. 1. Comparison of the composite salivary progesterone profiles of runners *(open squares)* and controls *(solid squares)*, aligned on day of menstrual onset. *Vertical lines* represent standard error of the group mean for that cycle day.

Although extreme levels of exercise thus often disrupt or shorten menstrual cycles, the study reported by Shangold et al.[8] suggests that milder regimens of exercise may lead to a suppression of luteal function that would not be observed from an examination of menstrual histories. Detection and quantification of mild luteal suppression require frequent monitoring of circulating progesterone levels. We have developed an assay of salivary progesterone to facilitate research in this area and used it to compare luteal progesterone levels in a group of recreational women runners with a group of nonathletic control subjects. In so doing we attempt to determine (1) whether luteal suppression is observable even among women following moderate exercise regimens and (2) how such suppression is characterized in terms of the timing, extent, and duration of progesterone secretion.

Material and methods

Subjects were recruited from an amateur athletic club in Boston and from the Harvard University community, although Harvard undergraduates were not included. Saliva samples from 15 cycles were collected from eight women identified as recreational runners averaging 12.5 ± 0.8 (mean ± standard error) miles of running exercise a week. Samples from 19 cycles were collected from a group of nine controls who reported no regular exercise habits. All subjects were screened for oral contraceptive use, recent pregnancy, and menstrual history. No attempt was made to control for marital status, socioeconomic status, or other life-style variables. In general, however, subjects were middle class, only three were married, and none reported occupational or living situations (such as night or swing shift work) which might be expected to cause aberrant hormone profiles. All reported regular menstrual cycles, with no significant difference in reported cycle length between groups (runners, 28.3 ± 0.6 days, versus controls, 28.3 ± 0.5 days). The two groups did not differ significantly in height (runners, 162.5 ± 2.2 cm, versus controls, 163.0 ± 1.3 cm) or age (runners, 30.7 ± 1.6 years versus controls, 29.3 ± 2.6 years). However, the runners were significantly heavier as a group (57.6 ± 2.6 kg versus controls, 50.7 ± 1.8 kg, $p < 0.01$, all levels of significance based on one-tailed t tests).

Each woman was provided with a set of polystyrene 12 × 75 collection tubes pretreated with sodium azide as a preservative. Samples of 2 to 5 ml of whole saliva were collected daily and stored at room temperature, the entire set being returned to the laboratory at the end of the month along with a record of menstrual dates and exercise. Samples were then frozen at −20° C until assayed. We have found a correlation of 0.89 ($p < 0.001$, $n = 20$) between progesterone values determined from matched frozen and unfrozen samples after 6 weeks. Subjects were requested to collect samples every day, but omissions occurred. For the 16 days preceding menstrual onset, the portion of the cycle analysed in this report, an average of 13.2 ± 0.7 sample days per cycle were collected from the runners

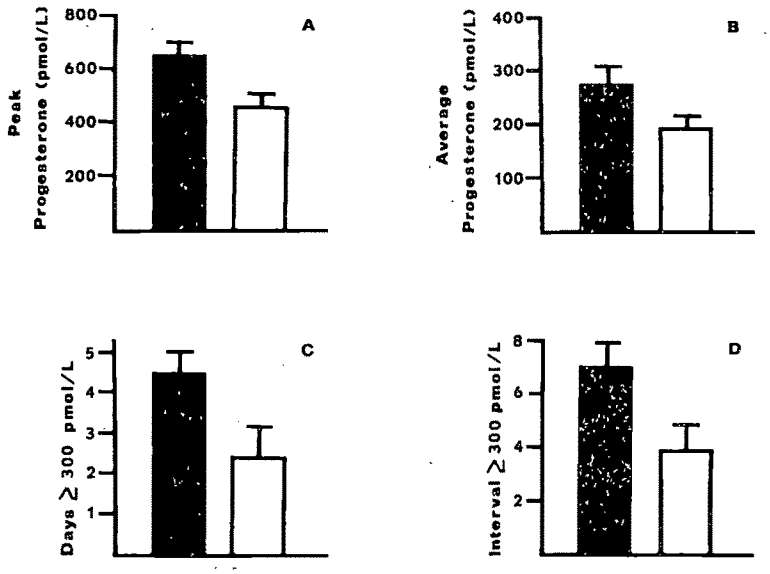

Fig. 2. *A*, Average peak luteal progesterone levels of the runners *(open bar)* and controls *(solid bar)*, $p < 0.01$. *B*, Average progesterone level over the 16 days before menstrual onset of runners and controls, $p < 0.05$. *C*, Average number of days with sample values ≥300 pmol/L among runners and controls, $p < 0.05$. *D*, Average interval between first and last observed value ≥300 pmol/L among runners and controls, $p < 0.05$. *Vertical lines* represent standard error. All p values based on one-tailed *t* tests.

and 12.5 ± 0.8 sample days per cycle from the controls ($p < 0.2$).

Samples were assayed for progesterone by radioimmunoassay, following a modified version of the method of Walker et al.[11] Assaying progesterone in saliva allows monitoring of ovarian function without undue disruption of a subject's normal routine. The high correlation between plasma-free and salivary progesterone levels has been well documented in a variety of experimental situations by many different investigators.[12] Because the relationship between plasma-free and salivary steroid levels is based on passive diffusion of free steroids across cell membranes,[13] there is no reason to expect that it would be affected by physiologic alterations in runners as a result of their exercise.

One milliliter of aqueous saliva was extracted twice in five volumes of diethyl ether with 1200 cpm of tritiated progesterone added as a tracer to quantify recovery, which averaged 80%. Extracted samples were dried under nitrogen and reconstituted in 1 ml of phosphate-gel buffer. Duplicate 400 μl aliquots were assayed in competition with 12,000 cpm of four-position tritium-labeled progesterone (New England Nuclear) for binding to a specific antibody, No. 337, generously supplied by Dr. Gordon D. Niswender. Reported cross-reactions of this antibody[14] indicated no need for chromatographic sample purification before assay. After 24-hour incubation at 4° C bound and free steroid were separated with dextran-coated charcoal, and radioactivity in the antibody-bound fraction was counted in a liquid scintillation counter. Two standard curves in triplicate were run with each assay. Results were quantified with a log-logit fit to the standard curve by programs supplied by Dr. David Rodbard. Assay sensitivity (smallest dose distinguishable from 0 with 95% confidence) was consistently <10 pg per assay tube, or approximately 50 pmol/L. Intra-assay and interassay variability were both below 13%.

Results

Fig. 1 illustrates the mean salivary progesterone levels, plus standard errors, determined for the runners and control subjects, aligned on the first day of menstruation. No difference in observed cycle lengths was found between the runners (27.5 ± 0.6 days) and the controls (27.0 ± 1.6 days). Nevertheless, the runners as a group displayed reduced levels of progesterone in the luteal phase of their cycles. Although the overall shape of the composite progesterone profile is strikingly similar in both groups, the runners have significantly lower peak progesterone levels (443 ± 58 pmol/L versus 655 ± 46 pmol/L, $p < 0.01$, Fig. 2, *A*), and lower average progesterone levels over the 16 days before menstrual onset (194 ± 24 pmol/L versus 287 ± 30 pmol/L, $p < 0.05$, Fig. 2, *B*). A sample value at least 2 SD above the follicular average of the controls, that is, >300 pmol/L, is operationally defined as indicating luteal activity. Such values are beyond the 95% confidence interval for follicular levels and thus represent statistically significant elevations of progesterone. Runners averaged fewer days of >300 pmol/L (2.5 ± 0.7 versus 4.5 ± 0.6 days, $p < 0.05$, Fig. 2, *C*) and a shorter

interval between the first and last days >300 pmol/L (4.0 ± 1.1 days versus 7.1 ± 1.0 days, $p < 0.05$, Fig. 2, *D*). Five of the 15 runners' cycles included no values >300 pmol/L and hence could not confidently be classified as ovulatory, whereas all the control cycles included values >300 pmol/L.

Although significant differences were observed in the progesterone levels attained by the two groups, no significant differences in the timing of the luteal phase were observed. The average day of peak progesterone secretion occurred 8.1 ± 0.7 days before menstrual onset in the runners versus 7.6 ± 0.5 days before menstrual onset in the controls. The first day of >300 pmol/L (for those cycles which attained this level) averaged 10.1 ± 0.7 days before menstrual onset for the runners versus 10.8 ± 0.8 days before for the controls, and the average interval between the first day >300 pmol/L and the peak day was 2.1 = 0.8 days for the runners and 3.2 ± 0.7 days for the controls.

It should be noted that our results do not address the physiologic mechanisms establishing the differences in observed salivary progesterone levels. Differences in salivary progesterone concentrations could result from differences in production rates, clearance rates, albumin binding, peripheral metabolism, or plasma volume.

Comment

Together with the results of previous studies, our results suggest that exercise may modulate female reproductive function in a continuous fashion, with mild exercise leading to mild impairment of function and more vigorous exercise leading to more extreme impairment. Low levels of exercise may first lead to a reduction in luteal progesterone levels, followed at increasing levels of activity by occasional and then frequent anovulatory cycles, shortened cycle length, oligomenorrhea, and finally amenorrhea. Only the more extreme end of this spectrum is visible based on menstrual characteristics, whereas the mild end requires regular monitoring of hormone profiles for detection.

Although clinical evidence has linked luteal phase defects with reduced fecundity,[15,16] it is not clear to what extent the level of progesterone suppression documented in this study may place implantation and early gestation in jeopardy. Nevertheless, the fact that such an effect can be observed at relatively low exercise levels, together with the fact that a growing number of women in their reproductive years regularly engage in recreational running and similar forms of aerobic exercise, renders the issue a matter of some public health concern.

Are preoperative antibiotics helpful in abdominal hysterectomy?

Cecilia C. Senior, M.B., B.S., B.Sc.(hons), Dip.Ed., and Stephen J. Steigrad, M.B., B.S.
Sydney, Australia

An open, randomized study to compare the effectiveness of triple-dose cefoxitin with the effectiveness of cephradine-tinidazole and with the result of nontreatment in patients undergoing abdominal hysterectomy was conducted from July 1983 to July 1984. One hundred ninety-nine patients were enrolled: 66 untreated control patients, 69 patients in the cephradine-tinidazole–treated group, and 64 patients in the cefoxitin-treated group. No significant differences were present in relation to age, pathologic condition, length of operation, blood loss, or length of hospital stay. That patients in both treatment groups had a lower incidence of postoperative febrile morbidity was not statistically significant. (AM J OBSTET GYNECOL 1986;154:1004-8.)

Key words: Preoperative antibiotics, hysterectomy

Hysterectomy is now one of the most frequently performed operations in Australia, and still 30% of women suffer morbidity resulting from operative site infection. This takes the form of abdominal wound infection, vaginal cuff infection, pelvic cellulitis, or pelvic abscess.

Various strategies, including systemic antibiotic prophylaxis,[1, 2] T-tube suction drainage of the retroperitoneal space,[3, 4] and topical irrigation of the surgical field with an aerosol antibiotic,[5] have been used effectively to reduce the incidence of pelvic cellulitis after vaginal hysterectomy. However, strategies to reduce morbidity after abdominal hysterectomy are not as well investigated or proved. In the Royal Hospital for Women, where approximately 75% of all hysterectomies are performed abdominally, the frequency of significant febrile morbidity is 32.7%, with 62% of all patients receiving antibiotics after hysterectomy. However, the effectiveness of antibiotic prophylaxis in reducing infection after abdominal hysterectomy is not well established.

Much of our knowledge of the cellular events leading to tissue infection is based on the thoughtful work of general surgeon John F. Burke,[6, 7] who concluded that there was a limited period when the operative site was receptive to the beneficial affects of antibiotic prophylaxis. He noted that the biochemical interaction between bacteria and host defenses began immediately when the organisms were inoculated, and to be effective in suppressing infection, antibiotics have to be given before the bacteria are introduced into the tissues. These original experiments have been verified by other studies.[8, 9]

Choice of antibiotic

Cefoxitin is a semisynthetic cephamycin antibiotic that is highly resistant to degradation by the β-lactamase enzymes produced by bacteria. It is active against all the clinically important gram-negative facultative bacteria except *Pseudomonas* and many *Enterobacter* species, as well as clinically important anaerobic organisms such as *Bacteroides fragilis*. It is inactive in vitro against most enterococci.

Cephradine is a semisynthetic cephalosporin antibiotic. Its range of activity is similar to that of cefoxitin except that cephradine has no activity against anaerobes, especially *B. fragilis*. This drug was chosen as the currently available intravenous cephalosporin in our hospital. No studies have been performed on cephradine specifically to determine whether the minimal inhibitory concentration is reached in pelvic wound fluid for expected contaminating flora. There is considerable variation within cephalosporins, and one cannot extrapolate from one to the other.[10]

Tinidazole is a nitroimidazole derivative that is claimed to be more bactericidal against *B. fragilis* than metronidazole[11] and to give higher and longer-lasting serum concentrations.[12, 13] In addition, 113 strains of anaerobic bacteria of the *Bacteroides, Peptococcus, Peptostreptococcus,* and *Clostridia* species have been shown to be sensitive to tinidazole.[14, 15]

Thus it seems that either cefoxitin or tinidazole-cephradine given preoperatively should cover the possible infective organisms and provide suitable prophylaxis against infection in pelvic tissues following abdominal hysterectomy.

Material and methods

An open, randomized study designed to compare the effectiveness of triple-dose cefoxitin with the effectiveness of cephradine-tinidazole and with the result of nontreatment in patients undergoing abdominal hysterectomy was conducted from July, 1983, to July, 1984, at the Royal Hospital for Women, Paddington, Australia. During this time, all patients undergoing hysterectomy were considered eligible for the protocol. Patients who had penicillin allergy, cephalosporin intolerance, or renal infection or who were currently taking antibiotics or requiring antibiotics for preexisting lesions (such as valvular heart disease) were automatically excluded from selection.

The patients were assigned to various treatment arms according to a predetermined randomized sequence. The attending physician was generally unaware of the medication given, and the assignment was performed by us. Treatment was organized as follows.

Those patients assigned to the cephradine-tinidazole group received oral tinidazole no greater than 12 hours before surgery (and generally on retiring): those on the morning list received the antibiotic on the evening before the operation, and those on the afternoon list received the antibiotic at 6 AM on the day of operation. One gram of cephradine was given intravenously as a bolus at induction of anesthesia. Those patients receiving preoperative cefoxitin received it as a 2 gm intravenous bolus injection at induction of anesthesia and at 6 and 12 hours postoperatively.

Hysterectomies were performed either by the senior medical officers at the hospital or by registrars in training supervised by a senior member of staff. Nearly all operations were performed with the patients under general anesthesia.

Table III. Procedures performed concurrently with total abdominal hysterectomy

	Control	*Tinidazole and cephradine*	*Cefoxitin*
Appendectomy	1	—	2
Retropubic urethropexy	2	—	1
Unilateral or bilateral adnexectomy	23	30	24

In the operating theaters, wound preparation of the patients was conducted according to the preference of the operating surgeon. It consisted of either povidone-iodine or 0.5% alcoholic chlorhexidine for skin preparation. All patients were catheterized before surgery. The duration of catheterization was not taken into account. The vulva and vagina were cleansed with 0.1% aqueous chlorhexidine. Alcoholic crystal violet was used to mark the vaginal vault.

Oral temperatures and other vital signs were taken every 4 hours postoperatively until the patient was discharged from the hospital.

Appropriate culture specimens were taken from the sites most likely to be infected as judged from the clinical evaluation. Specimens for other routine investigations, including vaginal swab and midstream urine or catheter specimen, were taken where indicated. Vag-

Additional antibiotics	37	56.9	27	47	25	41.6
Hospitalization days	8.0 ± 1.5		7.9 ± 1.9		8.3 ± 1.8	

inal cuff specimens were not obtained unless there was discrete loculation of serosanguineous or purulent fluid at the vaginal apex.

Follow-up. Early follow up consisted of routine postoperative care and close attention to physical findings. The care was performed by the attending physician and his registrars (not by us). With any suspicion of infection, cultures of the involved sites were grown. Positive physical findings of signs of inflammation were noted on the hospital charts.

Late follow-up was done because some postoperative pelvic infections are insidious. A report was received from each surgeon after the patient had been examined at the postoperative visit. All infections not noted in the hospital should have become evident within this time. After this examination the study was terminated with respect to each patient.

The following criteria were used to define infection-related morbidity: (1) febrile morbidity, determined by two oral temperatures greater than 38° C taken at least 4 hours apart (excluding the day of surgery); (2) pelvic (vaginal cuff) cellulitis, determined by persistent temperature elevation in association with abdominopelvic pain, vaginal cuff tenderness, and localized pelvic peritoneal irritation; (3) pelvic (vaginal cuff) abscess, demonstrated by discrete loculation of purulent fluid at the apex of the vaginal vault and by drainage of infected material on probing of the suture line; (4) urinary tract infection, with the diagnosis based on clinical symptoms suggesting cystitis or pyelonephritis and confirmed by bacteriologic culture; (5) wound infection indicated by warmth, erythema, induration, pain and/or tenderness, as well as overt purulent drainage at the site of the surgical excision; and (6) the need for additional antibiotics.

Results

One hundred ninety-nine patients were enrolled in the study. Sixty-six of these patients were control subjects. Sixty-nine patients received tinidazole and cephradine, and 64 patients received cefoxitin. The average age of the control group was 43.2 years, that of patients who received tinidazole and cephradine was 44.1 years, and that of the cefoxitin group was 45.1 years. These differences are not statistically significant. The groups were not analyzed with respect to racial composition, gravidity, parity, or socioeconomic class. Eighty percent of patients in all groups were premenopausal. There is no significant difference between duration of operation and intraoperative blood loss (Table I).

Each group had comparable pathologic conditions (Table II).

Table III shows that the three groups had similar additional surgical procedures performed at the time of hysterectomy.

Table IV shows the postoperative complications experienced by the three groups.

Patients in both treatment groups had lower incidences of postoperative temperatures (as defined above), of proved urinary tract infection, and of wound infections (Table IV). The postoperative use of antibiotics was marginally reduced. The duration of hospitalization was not reduced. As shown by a χ^2 test, none of these differences are statistically significant. There were no patients in any group who had positive blood cultures, septic shock, or septic pelvic thrombophlebitis. There were only three patients—two control subjects and one treated patient—who required readmission for management of delayed sepsis. One control patient developed a wound abscess and a pelvic abscess and subsequently developed a pelvic hematoma. Another control patient developed a large, infected wound hematoma that required evacuation. One of the cefoxitin patients developed a wound sinus from which *Pseudomonas* was cultured. These three problems were late complications. These complications are not statistically significant. Several patients developed vault granulation tissue that required treatment, and another patient required resuturing of the vaginal vault. In this survey there is no statistical difference between patients treated preoperatively with tinidazole and cephradine and those treated preoperatively with triple-dose cefoxitin. In all, the incidence of significant infections or complications of 1.5% is exceedingly low.

Comment

There are at least 18 different reports on prophylactic antibodies in abdominal hysterectomy. Authors of twelve articles[4, 16-26] found that they were beneficial, and the authors of six articles[14, 27-31] did not.

In certain instances, antibiotics have been continued for 4 or 5 days following surgery. Such an extended use of antibiotics constitutes a therapeutic rather than a prophylactic regimen. In fact, the continuation of antibiotics up to 12 hours after operation, as performed in this trial, was requested by the suppliers of cefoxitin and is not consistent with Burke's original findings.[6, 7] Many investigations have failed to show that an extended course of antibiotics is significantly more effective than preoperative antibiotics. Moreover, an extended course of antibiotics does not render the operative site bacteria free.[24]

Another problem in comparing results is that there are different criteria for the definition of febrile morbidity, with cutoff temperatures of 37.8°, 38°, and 38.3° C being used in different series. Ledger and Kriewall[32] have proposed a "fever index" as an evaluation of these infections. This fever index is the number of febrile degree-hours above 99° F, excluding the day of surgery. This definition has not been used here: however, a crude estimation of the amount of fever has been performed: 32.3% of control subjects had two or more temperatures greater than 38° C, and 20% of patients had more than two temperatures greater than 38° C, with an average of 4.6 temperatures greater than 38° C. In the tinidazole-cephradine group, 22% met the criteria of standard febrile morbidity and 10% had an average of four temperatures at or greater than 38° C. The corresponding figures for cefoxitin are 25% and 11.6%, with an average of 3.7 temperatures. However, when the figures were analyzed with the χ^2 test, they were not statistically significant.

Febrile morbidity is not an accurate measure of treatment outcome because not all patients with febrile morbidity had overt clinical infections. However, since most practicing gynecologists within this study group use morbidity as an indication to prescribe antibiotics, the reduction of the temperature itself reduces the postoperative use of antibiotics; χ^2 analysis shows that this reduction in antibiotic use is not statistically significant. There was a great reluctance to perform a white blood cell count to determine whether significant infection was present. It seems apparent, from the rate of postoperative use of antibiotics, that a persistent low-grade temperature, irrespective of physical findings, is equated with operative site infection if urinary tract and wound infections have been excluded. Vaginal cultures were rarely grown. This attitude can be justified by the information acquired by Ohm and Galask.[27] Although this response is not intellectually satisfactory, practically it does not appear to be associated with any obvious harm to the patient.

In conclusion, on the basis of the present data and our literature review, the following conclusions appear to be justified:

1. Limited preoperative antibiotics appear to reduce the incidence of urinary tract infection after abdominal hysterectomy. The incidence (7%) is very low in the control group. Moreover, lower urinary tract infections rarely are a cause of serious morbidity in gynecologic patients, and the infections respond rapidly to oral antibiotics.

2. Prophylactic or preoperative antibiotics have not consistently reduced the incidence of pelvic cellulitis in other trials, nor do they appear to have markedly reduced the incidence in this survey.

3. Although there is a 10% reduction in the incidence of febrile morbidity and a 10% to 15% reduction in the use of postoperative antibiotics, these results are not statistically significant.

4. The incidence of major pelvic abscesses is so infrequent that a significant difference between control and drug regimens was not apparent.

Therefore, in patient populations such as ours, in which the incidence of significant postoperative febrile morbidity is low and serious sequelae of operative site infection are rare, the prevention of this possible outcome is not an obvious justification for the routine use of preoperative antibiotics.

The further rationale for use of preoperative antibiotics is the prevention of wound infection. However, the incidence of significant wound infection in our study group is so low that it does not comprise an adequate justification for the use of preoperative antibiotics.

Despite the apparent lack of established benefits of systemic antibiotic prophylaxis, however, antimicrobial agents should be given to a patient population with an inherently high risk of sepsis. This criterion does not appear to apply to our population, nor is it possible to identify a subset of our population (excluding patients with malignant disease) that may benefit from such prophylaxis. Indeed, it can be argued that antibiotic prophylaxis may, in fact, be harmful in that it may exert unfavorable selective pressure on the microbiologic flora and cause untoward side effects in selected individuals. Broad-spectrum antibiotics, such as cefoxitin, may best be reserved for treatment of acute infection.

Cardiorespiratory fitness evaluation in climacteric women: Comparison of two methods

Morris Notelovitz, M.D., Ph.D., Carol Fields, M.P.E., Kim Caramelli, M.P.E., Molly Dougherty, R.N., Ph.D., and Anna L. Schwartz, B.S.
Gainesville, Florida

Middle-aged women are becoming increasingly interested in aerobic exercise. For exercise to be meaningful, training needs to be performed at 70% to 85% of $\dot{V}O_{2max}$ for 20 minutes, three times weekly. The graded exercise test is the standard method used to determine maximum oxygen uptake, but this test is impractical for use in clinical practice. A cross-sectional study evaluated 163 women between 35 and 75 years of age by graded exercise test and compared the result with a matched group of 121 women tested by bicycle ergometer (predicted maximum oxygen uptake). Bicycle testing and the graded exercise test had a similar range of values; this was confirmed by 29 climacteric women performing both tests ($r = 0.789$). Menopausal status has no effect on cardiorespiratory fitness: the predicted maximum oxygen uptake of age-matched menstruating women was 27.4 ± 6.3 ml/kg/min and that of nonmenstruating women was 25.3 ± 4.2 ml/kg/min ($p > 0.05$). Bicycle ergometry can thus be used as a screen to determine the cardiorespiratory fitness status of climacteric women. (Am J Obstet Gynecol 1986;154:1009-13.)

Key words: Cardiorespiratory fitness, climacteric, maximal $\dot{V}O_2$, predicted $\dot{V}O_{2max}$, exercise prescription

It has become increasingly apparent that cardiorespiratory fitness may play an essential role in preventing cardiovascular disease and in controlling many of its risk factors. Today heart disease is the leading cause of death in the United States, affecting both men and women. In women it is most prevalent after the menopause; postmenopausal women have three times the cardiovascular disease incidence of premenopausal women.[2]

The current "fitness craze" has encouraged many people to begin programs of regular exercise, although these are primarily unsupervised and inconsistent in nature. The American College of Sports Medicine, in establishing guidelines[3] for exercise programs in adults, suggests that for individuals 35 years of age and older (and symptomatic individuals under 35) a medical evaluation be given before any major change in exercise habits. This evaluation should include a comprehensive medical history, including a personal and family history and current health habits such as smoking, medications, diet, etc. A 12-lead resting electrocardiogram and monitoring of blood pressure is also suggested, followed by an electrocardiogram-monitored graded exercise test. The graded exercise test can be used to measure the functional capacity of the patient and assess cardiorespiratory fitness and can serve as a basis for exercise prescription.

There are many protocols for graded exercise testing, all of which accomplish essentially the same thing, although some may be more suitable for a given population or a particular setting than others.[4] A graded exercise test is classified as either maximal or submaximal. A maximal test involves imposing progressively increasing workloads on the exercising subject until exhaustion or significant signs of intolerance to the activity are demonstrated. This type of test is most often used for direct measurement of maximum oxygen uptake ($\dot{V}O_{2max}$), the most accurate assessment of cardiorespiratory fitness.[5] This test, which requires the collection and analysis of expired air samples, is usually performed in a laboratory and is not well suited to use in everyday clinical practice. Submaximal testing, on the other hand, is more ideally suited to the practicing physician and his patients. A bicycle ergometer is commonly used; the patient rides against a progressively increasing workload until a given heart rate is attained, from which the workload is calculated. The point at which this criterion is met can be used to estimate $\dot{V}O_{2max}$.[6]

Several studies have shown that predicted oxygen uptake testing correlates well with observed maximal testing when corrected for age,[7] but none of these stud-

Estradiol (pg/ml)	146.2 ± 18.7	19.5 ± 3.5

ies have examined climacteric women. This investigation was concerned with three main issues: (1) We compared the range of values derived from women aged 35 to 75 performing maximal $\dot{V}O_2$ testing with values in a similar group who were evaluated for $\dot{V}O_{2max}$ by means of a submaximal bicycle test. (2) We compared maximal and submaximal values by having the same subject perform both tests. (3) Since the onset of the menopause has been linked with an abrupt change in the cardiorespiratory fitness of women,[8] a subgroup of women was studied to see whether the menopause per se had any effect on cardiorespiratory function.

Methodology

All of the subjects were evaluated at the Center for Climacteric Studies Wellness Laboratory after informed consent had been obtained and a full physical examination performed. The subjects reported to the laboratory between 7:00 AM and 9:00 AM after a 12-hour fast and having had approximately 8 hours of sleep the previous night. The subjects were instructed to abstain from nicotine, caffeine, and alcohol and were asked not to exercise on the day preceding the test.

One hundred sixty-three healthy sedentary women (group 1) between the ages of 35 and 75 years were accepted as subjects for maximal testing after being screened for cardiovascular normalcy by a 12-lead electrocardiogram stress test and physical examination. The $\dot{V}O_{2max}$ was elicited by a modified Balke and Ware[9] treadmill protocol. The speed of the treadmill remained constant at 3.0 mph (versus 3.3 mph) throughout the test, while the elevation increased 1% each subsequent minute until either the subject declared fatigue or $\dot{V}O_2$ values failed to increase with increasing workload. Each subject's $\dot{V}O_{2max}$ was directly assessed by means of a Beckman Metabolic Measurement Cart. An electrocardiograph was used to monitor lead V_5 during the test; heart rates were calculated from the electrocardiogram printout obtained every minute.

One hundred twenty-one women (group 2) who met the same criteria were selected for participation in a study with the use of submaximal testing to predict $\dot{V}O_{2max}$. Each subject also underwent a complete physical examination, and a resting electrocardiogram was obtained. A submaximal bicycle ergometer test, as described by Åstrand,[6] was used to estimate $\dot{V}O_{2max}$.

The physical characteristics of the subjects who participated are described in Table I. They were closely matched as regards their mean age height, and weight ($p > 0.05$).

To examine the reproducibility of the tests in women evaluated by both the treadmill and ergometer techniques and to differentiate between the effects of menopause and aging, two further subgroups were chosen. Twenty-nine women participating in an ongoing exercise program were selected to have both the treadmill and ergometer tests (group 3). Their mean age was 55.6 ± 9.1 years. All were postmenopausal and had been trained for a minimum of 3 months. Ten were treadmill walkers, nine stationary bicyclers, and 10 exercised on Nautilus (muscle-strengthening) equipment. They were evaluated as indicated above before entry into the study and had a treadmill and ergometer test on two separate occasions. The interval between testing was <1 month. The order of testing was randomly selected.

To test for the effect of the menopause on cardiorespiratory fitness, women aged 45 to 55 from the ergometer-tested group were divided according to whether or not they were still menstruating. Premenopausal or postmenopausal status was confirmed by hormonal analysis and by menstrual pattern; postmenopausal women were required to have been amenorrheic for at least 1 year. The hormonal analysis was per-

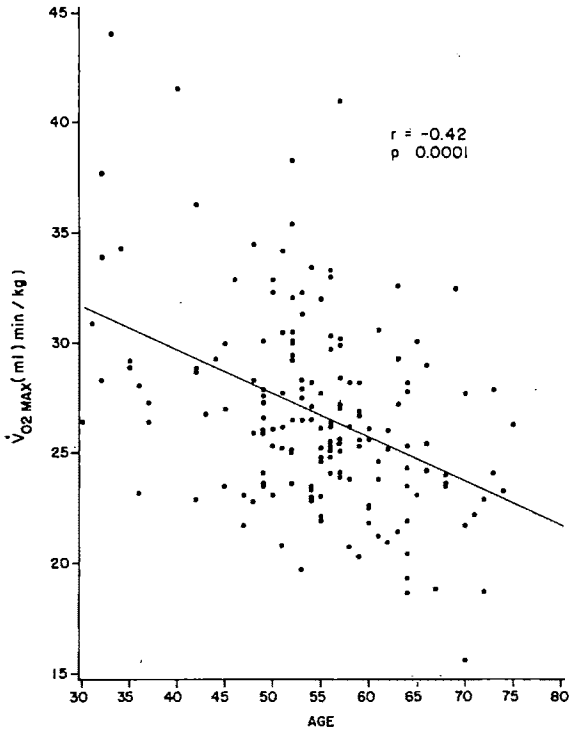

Fig. 1. Maximal oxygen uptake measured by a modified Balke and Ware treadmill procedure in 163 healthy climacteric women.

formed from blood samples obtained between 8:00 AM and 9:00 AM, according to methods described in detail elsewhere.[10] As reflected in Table II, serum luteinizing hormone and follicle-stimulating hormone levels were significantly higher in the nonmenstruating women ($p < 0.0001$), and the respective estradiol and estrone levels were significantly lower ($p < 0.0001$). The menstruating women were slightly younger (48.7 ± 0.4) than their amenorrheic peers (52.2 ± 0.4), but the difference was not statistically significant.

The data obtained were expressed as means and analyzed by an independent *t* test to determine whether significant differences existed between the groups.

Results

Table III describes the observed (measured) and the estimated $\dot{V}O_{2max}$ data of the two groups. Subjects were grouped by age and manner of assessment. There were no significant differences in mean $\dot{V}O_{2max}$ ($p > 0.05$) in any age group between those subjects who underwent maximal testing (group 1) and those who participated in submaximal testing (group 2). Similarly, the range of values for subjects in both groups showed no significant differences. The only apparent difference between these two groups was seen in the rate of change in $\dot{V}O_{2max}$ in successive decades. The measured $\dot{V}O_{2max}$

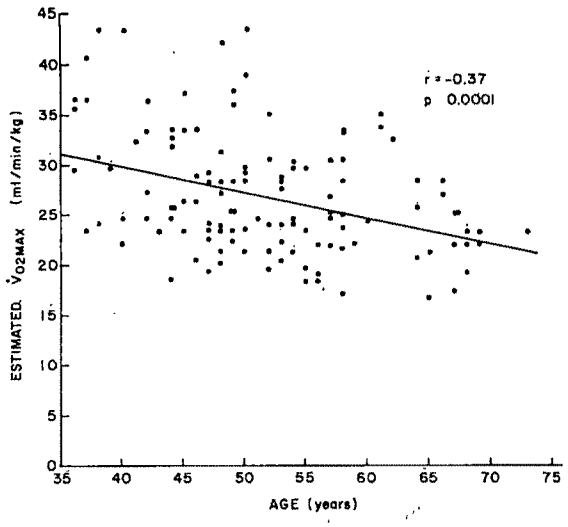

Fig. 2. Predicted maximal oxygen uptake determined by the Åstrand ergometer method in 121 healthy climacteric women.

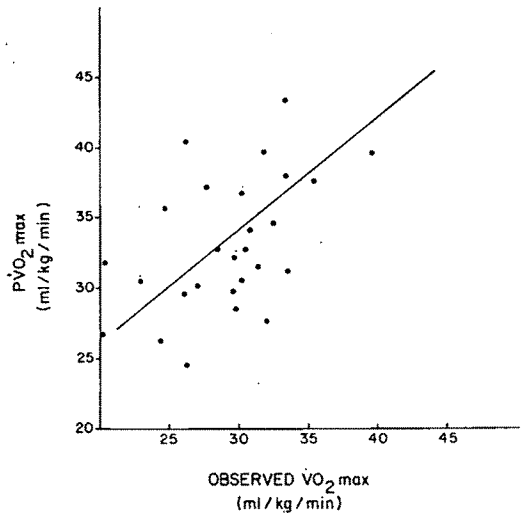

Fig. 3. Correlation between predicted and observed $\dot{V}O_{2max}$ derived by 29 women exercising on an ergometer ($P\dot{V}O_{2max}$) and treadmill testing (*observed* $\dot{V}O_{2max}$) ($r = 0.789$).

group showed an average decrement of 5.5% of $\dot{V}O_{2max}$ with each succeeding decade between ages 35 and 75 (Fig. 1), while the estimated $\dot{V}O_{2max}$ group lost an average of 7.4% of aerobic capacity each decade (Fig. 2).

The measured $\dot{V}O_{2max}$ of the 29 exercising women (group 3) participating in both test modalities was 28.6 ± 4.9 ml/kg/min, and the predicted $\dot{V}O_{2max}$ (determined with the ergometer) 32.5 ± 5.3 ml/kg/min. When the latter result was calculated with the recommended Åstrand age-corrected factor,[7] the mean predicted $\dot{V}O_{2max}$ was 23.4 ± 4.9 ml/kg/min. This result correlated closely with the direct measured result (r value = 0.789) (Fig. 3).

Table III. Maximal oxygen uptake value by age group for measured and estimated testing

Age group	$\dot{V}O_{2max}$ (ml/kg/min)	
	Measured (group 1)	Estimated (group 2)
35-44 yr	n = 13	n = 30
Mean	29.0	29.9
SD	4.9	6.5
45-54 yr	n = 60	n = 47
Mean	27.4	27.7
SD	3.9	8.0
55-64 yr	n = 70	n = 24
Mean	25.9	25.3
SD	3.8	5.3
65-75 yr	n = 20	n = 10
Mean	24.2	23.3
SD	4.0	3.1

No significant difference was found in the mean estimated $\dot{V}O_{2max}$ of premenopausal and postmenopausal women of similar age (Table II). Those women still menstruating had a slightly higher mean $\dot{V}O_{2max}$ (27.4 ± 6.3 ml/kg/min) than their nonmenstruating counterparts (26.3 ± 4.7 ml/kg/min), but this difference was not significant ($p > 0.05$).

Comment

Physical exercise performed at activity levels <50% of maximum heart rate can be maintained for several hours; to achieve physical fitness and its associated benefits, training needs to be performed at 70% to 85% of maximum heart rate for at least 20 to 40 minutes three times per week. Training levels sustained in excess of this range could be harmful to individuals with asymptomatic cardiovascular disease. For sedentary individuals who wish to participate in meaningful exercise, the graded exercise test is as integral a part of screening a patient as is the medical history. The graded exercise test is used to determine patient response (heart rate, blood pressure, electrocardiogram) to increasing intensity of exercise and can be used to determine $\dot{V}O_{2max}$, a measure of cardiorespiratory fitness that is representative of the efficiency of the oxygen transport system.[5] The $\dot{V}O_{2max}$ (or an estimate of such a value) is thus an important key to determining a proper exercise program. Individualized prescriptive exercise programs can be designed by use of a percentage of this value for the intensity level at which the exercise program should be performed. It can also serve as a measure of the conditioning effect of training by the incorporation of periodic $\dot{V}O_{2max}$ retesting into the program.

There is a gradual loss of $\dot{V}O_{2max}$ with age of slightly less than 1% per year in sedentary individuals, which becomes more apparent after about age 50. The rate of decline in $\dot{V}O_{2max}$ is usually, as in this study, determined by cross-sectional sampling of healthy individuals of different ages.

Table IV. Guidelines for fitness assessment by maximal oxygen uptake of healthy women aged 30 to 70 years

Age group	$\dot{V}O_{2max}$ (ml/kg/min)				
	Poor	Fair	Average	Good	Excellent
30-39 yr	<20	20-27	28-33	33-44	45+
40-49 yr	<17	17-23	24-30	31-41	42+
50-59 yr	<15	15-20	21-27	28-37	38+
60-69 yr	<13	13-17	18-23	24-34	35+

Adapted from Exercise Testing and Training of Apparently Healthy Individuals: A Handbook for Physicians. ●●●, American Heart Association, 1972:15

Dehn and Bruce[11] in a longitudinal study of healthy men determined that the coefficient for the rate of change was twice that determined by cross-sectional data. The decline in $\dot{V}O_{2max}$ reflects a loss of functional capacity, which may be attributed in part to the natural deterioration of the aging process and partly to age-related decrease in activity. The decline in maximal oxygen uptake with age is less pronounced in men who are habitually physically active, as compared with inactive individuals.[11] However, a study of physically active Swedish women,[12] who were assessed 20 years after the initial test, noted a 19% reduction in the subjects' maximal oxygen uptake values: 47.6 ± 0.7 versus 38.4 ± 0.7 ml/kg/min. Given the cross-sectional nature of our study and the sedentary female population studied, the directly measured $\dot{V}O_{2max}$ loss of 5.5% per decade (group 1) is less than that expected. However, the result is consistent with the predicted values obtained in the matched group (group 2) evaluated by ergometry—7.4% per decade. The values obtained in our women who were directly measured are compatible with those obtained by others for sedentary middle-aged women.[13]

By notation of the plateau of oxygen uptake with intense and prolonged exercise on the graded exercise test, it is possible to accurately determine the "true" point of maximal oxygen uptake. Higher values for $\dot{V}O_{2max}$ are thus usually obtained with the treadmill test. Walking, as in the graded exercise test, is more compatible with everyday activities than cycling, which is a "foreign" activity to middle-aged women in the United States. The greater observed $\dot{V}O_{2max}$ in our trained subjects (28.58 ± 4.86 ml/kg/min) could be explained by these factors and was therefore an expected result. The graded exercise test correlated well ($r = 0.789$) with the ergometer-devised test, thus confirming the experience of others involving male subjects.[7]

Although a reduction in $\dot{V}O_{2max}$ occurs in both men and women, it has been suggested that the onset of menopause may contribute to the intensified decline in aerobic capacity that appears near age 50.[14] When 45- to 55-year-old women were divided into menstruating and nonmenstruating groups, no significant difference was seen in mean estimated $\dot{V}O_{2max}$ of these women, supporting recent research showing that the menopause per se does not play a significant role in the decline of $\dot{V}O_{2max}$ with age.[15] The functional loss in the perimenopause may be curtailed by a program of regular physical activity. Cowan and Gregory[15] reported that premenopausal women (mean age 41.3 ± 4.4 years) who trained for 9 weeks had a 12.1% improvement in $\dot{V}O_{2max}$, and postmenopausal women (mean age 56.7 ± 5.2 years) who trained for a similar period had a 19% improvement.

On the basis of the documented decline in both maximal and submaximal testing in our laboratory (Figs. 1 and 2), the guidelines for evaluating the fitness status of climacteric women, with the use of either method, are compatible with those published previously (Table IV). Guidelines such as these are useful when one is evaluating a patient before prescribing exercise. It can serve as a reference point for the physician and his patient to determine her fitness status relative to that of other women in her age group and to provide a baseline value from which to start a program and measure improvement. Bruce et al.[16] recently reported that 63% of their patients attributed a change in one or more risk factors and health habits to a graded exercise test; persons with an abnormal result were motivated the most. Exercise testing may thus play an important part in stimulating women to participate in and continue with meaningful exercise.

In conclusion, a thorough medical examination, which includes testing of cardiorespiratory function, is advisable for patients adding regular exercise to their daily routine. Such an evaluation will ensure safer participation and will add ease and consistency to the monitoring of their progress. In addition, periodic examinations that show progress may help to establish and maintain greater patient rapport and encourage the compliance needed to achieve physical fitness.

The data from this comparative study indicate that bicycle testing for the estimation of $\dot{V}O_{2max}$ will elicit a range of values similar to those derived from maximal testing with a treadmill and the direct measurement of expired gases. Submaximal testing can thus be used as a screen to determine the cardiorespiratory fitness status of climacteric women. It is the method best suited for use in clinical practice because of its ease of administration. This is true irrespective of the menopausal status or fitness of the patients concerned. Patients at high risk for cardiovascular disease and those classified as having fair-poor fitness (as measured by ergometry) require more detailed evaluation before they embark on a prescribed exercise program.

We thank the following individuals for their help: Chris Zauner, Ph.D., Keith Johnson, M.D., Julie Tjapkes, R.N., and Karen Putney, R.N.

Influence of breast-feeding on the restoration of the low serum concentration of vitamin E and β-carotene in the newborn infant

Enrique M. Ostrea, Jr., M.D., James E. Balun, B.S., Ruth Winkler, R.N.C., and Thomas Porter, B.S.
Detroit, Michigan

Vitamin E and β-carotene are two important natural antioxidants. However, the mean (± SD) serum concentrations of β-carotene in the cord blood of term (17.9 ± 4.4 μg/dl) and preterm (14.04 ± 4.7 μg/dl) infants are one eighth the concentration in the maternal serum (131 ± 43 μg/dl). Likewise the serum concentrations of vitamin E in the term (0.31 ± 0.09 mg/dl) and preterm (0.29 ± 0.08 mg/dl) infants are one-third the concentration in the maternal serum (0.97 ± 0.16 mg/dl). Human breast milk, particularly colostrum, contains very high concentrations of both vitamin E (3.28 ± 2.93 mg/dl) and β-carotene (213 ± 166 μg/dl). Thus the breast-fed, term infant attains serum levels of both vitamin E and β-carotene comparable to those in the adult within 4 to 6 days of breast-feeding. This study shows that the seeming barrier in the fetus to access to the antioxidants vitamin E and β-carotene, in utero, is rapidly corrected and the substances are replenished postnatally through breast-feeding. This study therefore alludes to the possible role of breast-feeding in providing for the infant's defense against oxygen toxicity. (Am J Obstet Gynecol 1986;154:1014-7.)

Key words: Antioxidant, vitamin E, β-carotene, breast-feeding

Vitamin E and β-carotene are two important natural antioxidants. However, infants are born with significantly lower serum levels of vitamin E and β-carotene than the mother,[1-4] and the reason still eludes us. It has been postulated that the susceptibility of the premature infant to oxygen injury may be one reason for this deficiency.[5] As far as we know, no information is available on the natural restoration of the plasma levels of vitamin E and β-carotene in the infant postnatally. The purpose of this study was to determine, in a prospective design, the impact of breast-feeding on the restoration of the serum levels of vitamin E and β-carotene in a group of term infants.

Material and methods

A profile of the cord serum concentrations of β-carotene and vitamin E in paired maternal venous blood and cord blood was first obtained in 28 premature and 31 term infants. The gestational age of the infants was assessed by physical examination according to the method of Ballard et al.[6] Likewise, a profile of β-carotene and vitamin E concentrations in breast milk was determined. Breast milk was serially obtained from the first to the fifth day from 19 lactating mothers, five of whom had premature infants and 14, term infants. The mothers were taking regularly prescribed vitamin supplements for pregnancy. One mother further supplemented her daily diet with carrot juice.

The effect of feeding on the serum levels of vitamin E and β-carotene was studied in two groups of cesarean section–delivered term infants,* either breast-fed (N = 16) or formula fed (N = 8) with Similac 20 or Enfamil 20. Serum samples were obtained from cord blood and every other day from each group of infants from the second day to the day of discharge (days 4 to 6). Informed consent was obtained. The study protocol was approved by the Wayne State University Human Investigations Committee.

β-Carotene and total vitamin E in the serum (or milk) was determined by the spectrophotometric method of Hashim and Struttringger,[7] modified as follows: Into a small centrifuge tube, add the following by Lang Levy pipette: 200 μl of serum (or milk), 200 μl of absolute ethanol, and 400 μl of heptane. Whirl into a vortex for 10 minutes. Centrifuge at 3000 rpm for 10 minutes. With a Lang Levy pipette, transfer 300 μl of the upper heptane layer to a microcuvette (International Crystal

*This study was confined to term infants because an adequate oral intake of milk was essential to the study. The infants delivered by cesarean section were chosen because of their longer stay in the nursery.

Table I. Levels of β-carotene and vitamin E in maternal serum and cord blood of premature and term infants (mean ± SD)

	Term (N = 31)	*Premature (N = 28)*
Infant		
Gestational age (wk)	39.7 ± 0.6	33.9 ± 3.0
β-Carotene (μg/dl)	17.9 ± 4.42	14.04 ± 4.74*
Vitamin E (mg/dl)	0.31 ± 0.09	0.29 ± 0.08
Mother		
β-Carotene (μg/dl)	131.0 ± 43	120.6 ± 49.9
Vitamin E (mg/dl)	0.97 ± 0.16	0.91 ± 0.17

*$p < 0.01$ by Student's *t* test.

Laboratory, 1 cm light path and 0.2 cm width). In a Zeiss PMII spectrophotometer, read absorbance of β-carotene at 452 nm, using heptane as a blank. Add 40 μl of bathophenanthroline reagent (Sigma), 0.147% in absolute ethanol. Add 20 μl of $FeCl_3 \cdot 6\ H_2O$ reagent (Sigma), 0.040% in absolute ethanol. Cover and shake. Read absorbance at 532 nm for vitamin E as soon as the blank stabilizes. Calculate the concentration of β-carotene and vitamin E from standard curves constructed from pure β-carotene and vitamin E solutions (Eastman Chemical Co.). A correction for the absorbance of β-carotene at 532 nm is necessary for the calculation of the vitamin E concentration. In this spectrophotometric assay of β-carotene and vitamin E, no interference was noted from bilirubin or unsaturated free fatty acids.

Statistical analyses were done by paired or unpaired Student's *t* test and by regression analysis.

Results

Higher levels of β-carotene ($p < 0.01$), but not vitamin E, were found in the cord blood of term versus premature infants (Table I). No significant difference was noted in the maternal plasma levels of β-carotene and vitamin E of either the premature or the term infants. A large gradient in β-carotene and vitamin E concentrations was noted between maternal plasma and cord blood levels—a ratio of 8 : 1 and 3 : 1 for β-carotene and vitamin E, respectively.

Significant correlations ($r = 0.35$; $p < 0.01$) were found between the cord serum level of β-carotene and the infant's gestational age (Fig. 1) and between the β-carotene level ($r = 0.44$; $p < 0.01$) in the cord blood and that in the maternal blood (Fig. 2). No significant correlation was seen between the cord vitamin E level and either the infant's gestational age or the maternal vitamin E level, nor was there a correlation between levels of maternal vitamin E and β-carotene and the infant's gestational age.

Human milk, particularly colostrum, contained very high levels of vitamin E and β-carotene (Table II). Mean concentrations of these substances were highest in breast milk of 1 to 3 days, after which their concentrations rapidly diminished. In comparison, the two formulas analyzed (Enfamil 20 and Similac 20) had negligible concentrations of β-carotene and had levels of vitamin E similar to those found in human milk at 4 to 5 days of age. Human milk obtained from mothers who had term or preterm infants showed no significant difference ($p > 0.10$) in levels of β-carotene or vitamin E.

The effect of feeding on the serum level of β-carotene and vitamin E in the infants is shown in Fig. 3. A steady and significant ($p < 0.01$) increase in the serum concentration of both β-carotene and vitamin E occurred in breast-fed infants from day 2 onward. The formula-fed infants experienced a significant rise only in vitamin E levels and not in β-carotene levels, essentially as a result of the negligible content of β-carotene in the formula (Table II). Within the limited period of the study, 7 of the 15 breast-fed infants attained comparable adult serum levels (≥40 μg/dl) of β-carotene within 4 to 6 days of breast-feeding. Likewise, 12 of the 16 breast-fed infants had comparable adult levels (≥0.60 mg/dl) of vitamin E at days 4 to 6 of breast-feeding.

Comment

The data from this study confirm previously reported observations that the fetus has markedly lower serum levels of β-carotene and vitamin E in comparison with the mother.[1-4] The reason for this discrepancy has so far been unclear. Vitamins are transported across the placenta through the mechanism of a simple or facilitated diffusion, active transport, or pinocytosis.[8] Many factors, such as lipid solubility of the substrate and placental age, thickness, and surface area, may further modify the rate of transfer of these substances.[9] Still other factors may influence the fetal serum concentration, such as levels of carrier protein in the fetus, occurrence of reverse transport, placental and fetal metabolism of vitamins, and tissue storage in the fetus.[8] The majority of the water-soluble vitamins (vitamin B groups and vitamin C) are transported by active processes resulting in fetal concentrations of these vitamins two to five times higher than those on the maternal side.[10] In contrast, the serum concentrations of lipid-

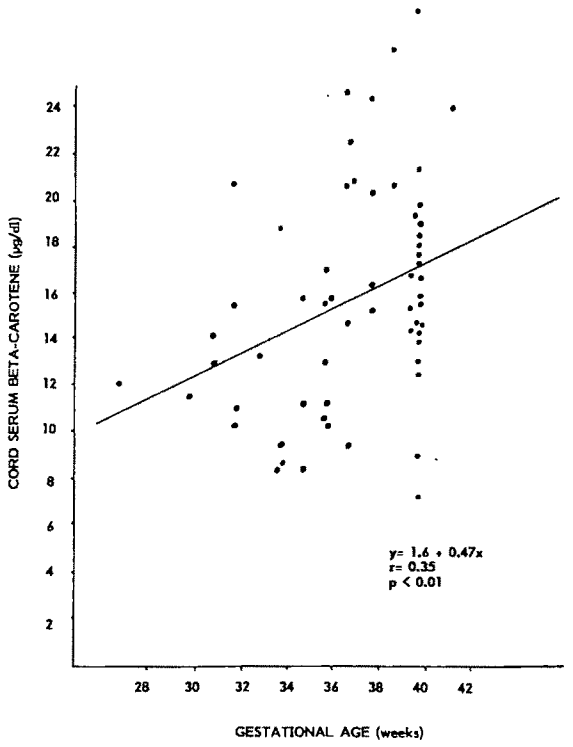

Fig. 1. Correlation between cord blood β-carotene level and gestational age.

soluble vitamins, vitamin E and β-carotene, in the fetus are generally less than the maternal levels.[1-4] Although this discrepancy may suggest such mechanisms as passive or facilitated diffusion, neither the actual mechanism of transport nor the factors affecting it are clear. For instance, megadose administration of vitamin E or β-carotene to mothers does not cause a commensurate rise in fetal serum levels,[2, 11, 12] as might be expected from a simple diffusion phenomenon. Whatever the reason, low serum levels of vitamin E or β-carotene in the fetus exist even among normovitaminemic mothers.[10-12] Thus it is reasonable to assume that the low serum levels of vitamin E and β-carotene in the fetus reflect a physiologic rather than a deficiency state.

Soon after birth, the situation changes. The breast-fed infants receive a high dose of both vitamin E and β-carotene in the breast milk, particularly in the colostrum. Consequently, as shown by this study, their serum β-carotene and vitamin E concentrations progressively increase, and within 4 to 6 days of breast-feeding, restoration to serum levels comparable to those in adults occurs in a significant number of the infants. Thus the seeming barrier to access to vitamin E and β-carotene in utero is rapidly corrected, and the two antioxidants are replenished postnatally through the breast milk. In contrast, the formula-fed infants do not show any increase in their serum β-carotene level. The reason is

Table II. Concentrations (mean ± SD) of β-carotene and vitamin E in human milk and in formula

	β-Carotene (µg/dl)	*Vitamin E (mg/dl)*
Human milk

that currently available formulas, unlike colostrum, do not contain any measurable amount of β-carotene (Table II). On the other hand, since formulas are fortified with vitamin E, formula-fed infants show a progressive increase in their serum vitamin E levels similar to those achieved among breast-fed infants. It is of interest to note that although breast milk contains a higher concentration of vitamin E than currently available formulas (Table II), the serum concentration of vitamin E attained in the breast-fed infant is not significantly higher than that seen in the bottle-fed infant (Fig. 3). The reason may relate to the bioavailability, absorption, and volume of distribution of vitamin E in the infant. For instance, it has been shown that to achieve and maintain a serum vitamin E concentration in the infant of 3 to 4 mg/dl, inordinately high doses of vitamin E (25 to 100 mg) have to be orally administered daily.[13]

Vitamin E and β-carotene are two important naturally occurring antioxidants in biologic systems: β-carotene functions as an avid singlet oxygen quencher,[14] and vitamin E protects principally against the peroxidation of lipids in cell membranes.[15] The antioxidant characteristics of these two substances have been involved or tested in various biologic and clinical studies.[13, 16] Therefore the access of the newborn infant to high concentrations of both antioxidants, vitamin E and β-carotene, in the breast milk alludes to an important role of breast milk—that of providing for the infant's defense against oxygen toxicity. This study, by design, was confined to a population of term infants. Although its results support the concept that breast-feeding provides for a replenishment of the antioxidant state in the newborn infant, it will be important to determine whether the same bioavailability of vitamin E and β-carotene occurs in the premature infant who is breast fed or otherwise given human milk, since the risk of the toxic effects of oxygen is particularly high in this group of infants.

Postpartum moods in men and women

David M. Quadagno, Ph.D., Laurie Ann Dixon, M.A., Nancy W. Denney, Ph.D., and Henry W. Buck, M.D.

Lawrence, Kansas, and Madison, Wisconsin

Twenty-one married couples, recruited from childbirth classes (mean age 29.6 years), were administered questionnaires measuring 20 different moods during the third trimester of pregnancy (prepartum period), during the postpartum period, and at 6 months after birth (follow-up period). In each questionnaire period individual questionnaires were filled out daily by both the mother and father for 10 consecutive days. The results indicated that the postpartum period, compared with the prepartum and follow-up periods, is an emotionally unique time but not a period marked by depression. The moods that were rated as being experienced more strongly by men and women during the postpartum period were associated with anxiety and concern for one's ability to cope such as "nervousness," "worried," "helpless," and "anxious" or positive emotions such as "enthusiastic" and "happy." It is concluded that men and women in this sample tend to experience the postpartum period in an emotionally similar way. (AM J OBSTET GYNECOL 1986;154:1018-23.)

Key words: Postpartum period, moods, women, men

The postpartum or puerperal period begins after the delivery of the child and ends approximately 6 weeks later when the reproductive tract returns to a normal nonpregnant condition. There is a wealth of literature concerning feelings of depression during the postpartum period. These feelings range from very mild "maternity blues" and "postpartum depression," which is characterized by a transitory state of tearfulness, depression, and anxiety, to rare cases of postpartum psychosis, which is a serious mental illness associated with the childbirth process and postpartum period.[1-5]

"Maternity blues" or "postpartum depression" has been reported for 20% to 89% of mothers, depending on the study.[4-7] Postpartum psychosis is a rarer phenomenon and has been reported as occurring in 3.0 to 3.6 per 1000 women.[8]

A variety of variables have been associated with postpartum depression, including age, a history of premenstrual tension, concern about the feeding habits of the baby, high neonatal risk, number of previous children, whether the woman is employed outside the home, and social, cultural, and personal expectations.[4, 5, 9, 10] The exact cause of postpartum depression is unknown, but several studies suggest it may have a hormonal basis associated with the dramatic changes in estrogen and progesterone levels during pregnancy and at the time of birth.[2, 4, 11, 12]

In spite of the fact that postpartum depression has traditionally been associated with the biologic mother, some studies have reported incidences of postpartum depression in other family members.[4, 7, 13-15] Atkinson and Rickel[15] found that 13% of their sample of middle-class men reported having felt depressed at some point in time during the 8 weeks after the birth of their first baby, and this was the same as the prepartum percentage. The men's depression was due, in part, to the fact that they viewed the baby in a less positive way than they anticipated they would before the birth of the baby. Zaslow et al.,[7] studying a sample of 57 middle-class families after the birth of their first child, found that 62% of the fathers and 89% of the mothers reported that they had experienced postpartum depression at some point in time in the 4 months since the birth of their babies. No data were provided for levels of depression for men and women in the period before the birth of the child.

The purpose of the present study was to further investigate mood changes in both men and women during the postpartum period. A group of expectant parents was studied at three points in time: prepartum period, postpartum period, and 6 months after the birth of the baby. During these three time periods both parents were asked to fill out questionnaires regarding 20 different moods to ascertain if the postpartum period produced markedly more negative moods than the prepartum and 6-month follow-up periods.

Method

Subjects. The subjects were 21 married couples recruited through a local hospital located in a city of 55,000 in the midwestern portion of the United States. All of the subjects were taking instruction in various methods of prepared childbirth. The mean age of the women was 28.4 years (range, 19 to 34) and the mean age of the men was 30.9 years (range, 20 to 46). All subjects were Caucasian, and 10 of the women and five of the men had a college education. Fifteen of the couples had no previous children, and six had one previous child. Nineteen of the husbands were present in the delivery room during the birth of the child.

Procedure. Questionnaires were distributed during the third trimester of pregnancy (prepartum period), during the postpartum period, and then again at 6 months after the birth of the child (follow-up period). In each questionnaire period individual questionnaires were filled out daily by both the mother and father for 10 consecutive days. Questionnaires were administered during 10 days rather than at a single session to minimize the effects of random fluctuations in mood. The subjects were told that the purpose of the study was to gather information about the moods of couples having a baby. All women were in the third trimester of pregnancy when the first set of questionnaires was given to the prospective parents. During the prepartum period a consent form, background information form, and the questionnaires were given to the couples. The couples were instructed to fill out a daily questionnaire for the next 10 consecutive days. They were further told that another set of questionnaires would be given to them as soon as possible after the birth of their child.

The second set of questionnaires was given to the parents within 24 hours of delivery, and in all cases the parents began to fill out the first of the 10 consecutive questionnaires within 2 days after the child's birth. One of the authors (H. W. B.), an obstetrician, evaluated the hospital records of the birth process. All 21 babies weighed at least 5 pounds at birth and any cesarean births or births with severe postpartum medical complications were excluded from this study.

Approximately 6 months after the birth of the child the parents were presented with the final set of questionnaires, and in all cases the parents began to fill out the questionnaires before the baby was 7 months old. The questionnaires that were filled out during the three periods contained the following 20 mood-related adjectives: nervous, lonely, self-confident, irritable, worried, content, depressed, angry, energetic, discouraged, sad, relaxed, miserable, pessimistic, enthusiastic, tearful, helpless, happy, anxious, and upset. The subjects

were asked to rate the extent to which each adjective described how they felt that day. The response alternatives were: not at all (scored 0), somewhat (scored 1), moderately (scored 2), very much (scored 3), and extremely (scored 4).

Results

The dependent variables were obtained by averaging the 10 ratings each subject gave for each of the individual moods during prepartum, postpartum, and follow-up periods. Separate 3 (time periods) × 2 (sex) × 21 (couples) analyses of variance were performed on these average scores for each of the 20 moods. Time period and sex were within-subject variables; sex was treated as a within-subject variable because the man and woman of each couple were not independent. Only the effects associated with sex and time period will be reported since differences between individual couples are not relevant to the questions addressed in the present study.

Time period was a significant source of variance for 10 of the 20 moods. At the postpartum period the subjects reported that they experienced more negative affect than they did at either the prepartum or the follow-up period; they were more nervous, less self-confident, more worried, less energetic, more tearful, more helpless, and more anxious. At the same time, however, they reported more positive affect as well; they were less angry, more enthusiastic, and happier. The means, SDs, F values, and p values are presented in Table I.

There were significant sex differences for 10 of the 20 moods. Men reported themselves to be significantly less lonely, irritable, depressed, angry, discouraged, sad, miserable, tearful, and upset than women reported themselves to be. Further, men reported themselves to be significantly more energetic than women. The means, SDs, F values, and p values for these 10 moods are presented in Table II.

There were significant interactions between sex and time period in the analyses of four moods—self-confident, miserable, enthusiastic, and tearful. The means, SDs, F values, and p values for these four interactions are presented in Table III.

Post hoc analysis was performed to further explore the interactions between sex and time period. An 0.05 level of significance was accepted for all post hoc analyses. The significant interaction between sex and time periods for the mood "self-confident" occurred because the ratings of self-confidence by the men did not change across the three periods, while the women rated themselves as significantly more self-confident during the follow-up period than during either of the other two periods.

For the mood "miserable" the interaction between sex and time periods occurred because, while the ratings of the men did not vary across the three periods, those of the women were significantly higher during the postpartum period than during either of the other two periods.

The interaction between sex and time periods was also significant for the mood "enthusiastic." Females reported significantly more enthusiasm during the postpartum and follow-up periods than during the prepartum period while men reported significantly more enthusiasm during the postpartum period than during the other two periods.

Finally, the interaction between sex and time periods was also significant for the mood "tearful." Both the men and the women were significantly more tearful during the postpartum period than during the other two periods. The women were also significantly less tearful during the follow-up period than during the prepartum period.

Comment

The first question that needs to be addressed with the results of the present study is whether the subjects—men or women—experienced postpartum depression. The results of the analyses of variance indicate that there were significant time period effects with 10 of the 20 moods being rated differently during the postpar-

tum period than during either the prepartum or the follow-up period. The subjects reported that they felt significantly more nervous, worried, anxious, helpless, tearful, happy, and enthusiastic, as well as significantly less angry, energetic, and self-confident at the postpartum period than during the other two time periods. For all of the moods for which there was a significant time period effect, the postpartum period was the time period that was rated differently from the other two, suggesting that the postpartum period is, emotionally, a somewhat unique period.

Although the results of the present study indicate that the postpartum period is an emotionally unique period, they do not indicate that it is marked by depression. The moods that were rated as being experienced more strongly during the postpartum period were not those typically associated with depression ("depressed," "discouraged," "sad," and "pessimistic"). Rather those rated higher during the postpartum period tended to be moods that were associated either with anxiety and concern with one's ability to cope ("nervous," "worried," "helpless," and "anxious") or with positive emotions such as "enthusiastic," "happy," and "angry" ("angry" decreased during the postpartum period).

In addition to these two main themes, subjects rated themselve as less energetic and more tearful during the postpartum period. It is, of course, not surprising that subjects would rate themselves as having less energy immediately after the birth of a child and during the early days of having a new infant in the home. The fact that "tearful" was rated differently during the postpartum period is more difficult to interpret because there is no direct evidence from the present study as to whether the subjects were feeling tearful for positive, joyous reasons or as a result of more negative feelings. The fact that the subjects reported being more happy, more enthusiastic, and less angry during the postpartum period while they did not report being more depressed, discouraged, sad, pessimistic, or upset, however, suggests that their increased tearfulness may have resulted more from positive affect than from negative affect.

On the basis of the significant time period effects, it appears that the postpartum period is a time of heightened emotions, associated not with depression but rather with anxiety, on the one hand, and increased positive affect, on the other hand. Individuals may be nervous and worried about their ability to cope with the demands of a new infant, but yet, at the same time, they seem to feel very positively about the experience.

The conclusion that the postpartum period was not marked by depression is supported not only by the significant time period effects but also by the absolute levels of depressive affect reported by the subjects. The subjects were asked to rate the extent to which they experienced each of the 20 moods on a scale from 0

(not at all) to 4 (extremely). The mean rating for each of the moods that might be associated with depressive affect (irritable, depressed, discouraged, sad, miserable, pessimistic, and upset) was always less than 1 and usually less than 0.5. This was true even during the postpartum period. It would be difficult to interpret such low ratings of depressive affect as indicating any degree of postpartum depression.

The second question that needs to be addressed is whether the husbands and wives responded in the same way, emotionally, to the postpartum period. There were significant interactions between sex and time period in only four of the analyses of the 20 moods. One of these interactions, the one for "tearful," occurred because the wives exhibited a more extreme change during the postpartum period than their husbands, but the ratings of "tearful" were evaluated in both wives and husbands during the postpartum period. Thus only three of the interactions indicate that wives and husbands responded differently to the postpartum period. First, the interaction between sex and time period for "self-confident" indicated that while the wives felt less self-confident during the postpartum period, their husbands did not. Second, the interaction for "enthusiastic" indicated that while both wives and husbands rated themselves as more enthusiastic during the postpartum period than during the prepartum period, only the husbands indicated a decrease in enthusiasm from the postpartum to the follow-up period. The wives rated themselves as just as enthusiastic during the follow-up period as they did during the postpartum period. Third, the interaction for "miserable" occurred because the wives rated themselves as more miserable during the postpartum period than during the other two periods while the husbands did not rate themselves differently across the three time periods.

The three interactions between sex and time period do not, in our opinion, alter the conclusions drawn on the basis of the main effects for time periods. Both the wives and husbands appeared to experience more anxiety and more positive affect during the postpartum period than during the other two periods. The only interaction that presents any difficuclty for the conclusions that were drawn on the basis of the main effects is that obtained for "miserable." On the basis of the main effects for time period, we concluded that there was no evidence for the postpartum period being associated with depressive affect. The fact that the wives rated themselves as more miserable during the postpartum period suggests that the wives may have experienced some heightened negative affect. However, it seems somewhat unusual that the wives would not also show increases in feelings of "irritable," "depressed," "discouraged," "sad," "pessimistic," and "upset" if they were experiencing depressive affect. It may well be that the wives rated themselves as more miserable during the postpartum period because of physical, rather than psychological, discomfort.

In addition to the time period effects and the interactions between sex and time periods, significant sex differences in mood ratings were also obtained for 10 of the 20 moods. Women rated themselves as more lonely, irritable, depressed, angry, discouraged, sad, miserable, tearful, and upset than men. The men rated themselves as more energetic than the women. These sex differences are difficult to interpret. It is not clear whether women experience a significantly greater degree of negative affect than men or whether women are simply more likely to report negative affect. Perhaps the fathers in our study returned to work and had limited involvement with the child during the postpartum period. The mothers, on the other hand, remained at home with the child and this social isolation could have contributed to the women's negative moods when compared to the husbands' moods.

In conclusion, the results of our study using parents recruited from childbirth classes indicate that the postpartum period is an emotional period for both men and women and that, for the most part, men and women tend to experience the postpartum period in an emotionally similar way. Both husbands and wives tend to rate themselves as more anxious and worried and as experiencing more positive affect. Our sample did not show the high levels of postpartum depression previously reported by others. This could be due to the fact that our participants were taking instruction in childbirth classes.

We wish to thank Madeline Moss, Phyllis Queen, Sandy Dolezal, Sheila Walasyek, Fran Williams, Jan Elder, and Jill Quadagno for their help during various phases of this study.

Effect of acetone precipitation on the clinical prediction of respiratory distress syndrome when utilizing amniotic fluid lecithin/sphingomyelin ratios

David W. Hobson, M.D., Thomas Spillman, Ph.D., and David B. Cotton, M.D.
Houston, Texas

Amniotic fluid lecithin-to-sphingomyelin ratios are widley used to predict fetal lung maturity. The inclusion of acetone precipitation in the determination of the lecithin/sphingomyelin ratio has been widely accepted as a necessary step for enhancing predictivity. The lecithin/sphingomyelin ratio of 181 amniotic fluid samples was analyzed with and without acetone precipitation. Sensitivity, specificity, and predictive values were compared. Although there was a significant difference in the numeric value ($p < 0.001$) between the two methods, the clinical prediction of the respiratory distress syndrome was not significantly enhanced by acetone precipitation. We conclude that acetone precipitation fails to improve the prediction of fetal lung maturity by lecithin/sphingomyelin ratio analysis. (AM J OBSTET GYNECOL 1986;154:1023-6.)

Key words: Acetone precipitation, lecithin/sphingomyelin ratio

Despite considerable controversy in the past, acetone precipitation before the measurement of amniotic fluid lecithin is still widely accepted as being indispensable. The rationale for the use of acetone precipitation has been that total amniotic fluid lecithin is not truly representative of "surface active" lecithin and that acetone precipitation is capable of separating the surface-active lecithin (disaturated lecithin) from the other lecithin components.[1] However, it has been shown that acetone precipitated extracts of amniotic fluid are not exclusively composed of disaturated lecithin.[2] Furthermore, the original study by Gluck et al.[3] suggesting acetone precipitation as necessary for the isolation of saturated lecithin ironically used a detection method that measured only unsaturated lecithin.[4]

Gluck et al.[3, 5] first reported that the respiratory distress syndrome in newborn infants could be predicted from measurements of the lecithin/sphingomyelin (L/S) ratio in amniotic fluid. With the inclusion of the acetone precipitation step in his procedure, Gluck et al.[6] reported an L/S ratio beyond 2.0 was associated with little or no risk for respiratory distress syndrome. However, the inclusion of the acetone precipitation step in determining the L/S ratio of amniotic fluid has never been shown by parallel testing of the same sample to enhance predicitivity. We therefore undertook a prospective study to determine the effect of acetone precipitation on the clinical prediction of respiratory distress syndrome.

Material and methods

Specimen collection. One hundred eighty-one amniotic fluid specimens collected from separate pregnancies of varying gestational ages were analyzed for phospholipid composition. The samples were analyzed regardless of the source of amniotic fluid (amniocentesis versus vaginal pool) or complications of pregnancy (Table I). Samples with trace meconium or blood contamination were included.

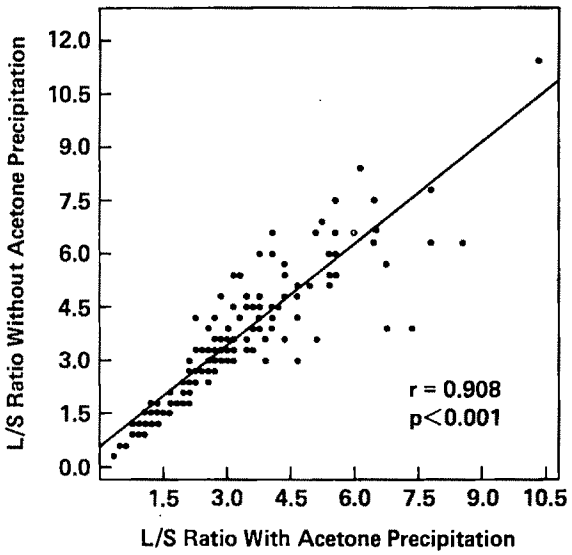

Fig. 1. Comparison of the L/S value without acetone precipitation to the same specimen when acetone precipitation was used.

Table I. Status of pregnancy in patients undergoing amniotic fluid analysis

Pregnancies	*No.*
Uncomplicated	100
Complicated by	
Rupture of the membranes >24 hr	15
Diabetes mellitus	
Class A	17
Class B	20
Class C, D, R	3
Hypertensive disease	19
Erythroblastosis fetalis	2
Abnormal placentation	5
Total	181

Specimen storage. Amniotic fluid specimens were immediately centrifuged on receipt at 1000 × g for 10 minutes and the supernatant decanted. If the determination of phospholipids was going to be done within 4 hours, the specimen was refrigerated. Otherwise, the centrifuged specimen was stored at −20° C until analyzed. All specimens were analyzed within 48 hours of being received.

Extraction. The supernatant was mixed with an equal volume of methanol before the addition of a third volume of chloroform. The phases were mixed vigorously for a few seconds and then centrifuged at 1000 × g for 10 minutes to separate the layers. The chloroform layer was decanted and evaporated to dryness at 37° C under a stream of air. The dried extract from 1 ml of amniotic fluid then underwent the acetone precipitation procedure while a duplicate aliquot of the same extract was reconstituted in chloroform for thin-layer chromatography.

Table II. Comparison of the ability to predict respiratory distress syndrome (RDS) by L/S ratio with and without acetone precipitation*

Test	*RDS*	*Nc RDS*	*Total*
L/S without acetone precipitation			
L/S ratio < 2.0	15	7	22
L/S ratio ≥ 2.0	2	150	152
L/S with acetone precipitation			
Acetone < 2.0	15	10	25
Acetone ≥ 2.0	2	147	149

*All samples were obtained ≤72 hours before delivery.

Acetone precipitation. One hundred microliters of cold, anhydrous acetone was added to the tube of dried extract, which had been placed in an ice bath for 2 minutes and the tube held on ice for an additional 5 minutes. The tube was then inverted, the acetone allowed to drain off, and a second 100 μl of cold anhydrous acetone added as a rinse and drained off immediately. Any residual acetone was dried with an air stream. The extract was reconstituted in chloroform and loaded onto the thin-layer chromatography lane next to the acetone-precipitated extract.

Chromatography. Extracts and standards in chloroform were streaked onto thin-layer chromatography plates (catalog No. 4865-82, Whatman, Inc., Clifton, New Jersey). After evaporation of the loading solvent at room temperature, the plates were allowed to develop for 70 minutes in tanks containing the following solvent mixture: 30 ml of chloroform, 25 ml of isopropanol, 25 ml of triethylamine, 9 ml of methanol, and 7 ml of water.[7] After development the plates were briefly air dried and heated to 160° C for 5 minutes before a cupric acetate reagent was applied.[8] Bands were identified by migration relative to known standard compounds. Both acetone-precipitated and non–acetone-precipitated extracts of the same amniotic fluid specimen were chromatographed on adjacent lanes of the same plate. Band intensities were determined by transmission densitometry. The densitometric ratio required for the heating standard (catalog No. LS30, Sigma Chemical, St. Louis) was 1.65 ± 0.20. Band development was at 160° C.

Clinical evaluation of infant outcome. Each infant's outcome was evaluated by two of the investigators (D. B. C. and T. S.), independent of the results obtained from amniotic fluid analysis. The following signs and symptoms were considered diagnostic of the respiratory distress syndrome: grunting, tachypnea, retraction, nasal flaring, cyanosis on room air, and a reticulogranular ground glass appearance with air bronchograms on chest x-ray examination. The necessity for oxygen therapy for a minimum of 24 hours was re-

Table III. Value of the different methods of L/S ratio determination in the prediction of respiratory distress syndrome (RDS)

Test	No. of infants examined	Sensitivity*		Specificity†		Predictive value of abnormal tests‡		Predictive value of normal tests§		Efficiency‖	
		n	%	n	%	n	%	n	%	n	%
L/S without acetone precipitation	175	15/17	88	150/157	95	15/22	68	150/152	99	165/174	95
L/S with acetone precipitation	175	15/17	88	147/157	94	15/25	60	147/149	99	162/174	93

The definitions given below which are used to establish the value of a diagnostic test are from reference 17.
*Number of L/S ratios <2.0 ÷ by number of infants with RDS.
†Number of L/S ratios ≥2.0 ÷ by number of infants without RDS.
‡Number of infants with RDS ÷ by number of infants with an L/S ratio <2.0.
§Number of infants without RDS ÷ by number with L/S ratios to ≥2.0.
‖Number of true positive tests + the number of true negative tests ÷ by total number of tests.

quired. The diagnosis of mild respiratory distress syndrome was made when an oxygen-hood was required to maintain oxygenation, moderate respiratory distress syndrome when continuous positive airway pressure was required, and severe respiratory distress syndrome when endotracheal intubation was required.

In cases for which the prediction of respiratory distress syndrome was tested, all infants were born within 72 hours of the amniotic fluid collection.

Results

We first compared the numeric result of the L/S ratio determined by the exclusion of the acetone precipitation step (nonprecipitated L/S) to the L/S ratio determined by the inclusion of the acetone precipitation step. With use of the paired Student's *t* test, there was a significant difference in the L/S ratio values obtained between the two methods ($t = 6.0$, $p < 0.001$). Calculation of the least-squares linear regression line showed that a nonprecipitated L/S of 2.0 was equivalent to an L/S with acetone precipitation of 1.9 (acetone-precipitated L/S ratio = 0.88 (L/S nonprecipitated) + 0.1; see Fig. 1).

Next we compared the clinical predictivity for respiratory distress syndrome of the nonprecipitated L/S values with the acetone-precipitated L/S ratios (Table II). There were 175 cases in which delivery occurred within 72 hours, 17 involving infants in whom respiratory distress syndrome developed (five cases were mild, four were moderate, and eight were severe). Prediction of respiratory distress syndrome on the basis of the nonprecipitated L/S ratio resulted in two false negative tests out of 152 mature tests (1.3%) and seven false positive tests out of 22 immature tests (31.8%). Prediction on the basis of the acetone-precipitated L/S ratio resulted in two false negative tests out of 149 mature values (1.3%) and 10 false positive tests out of 25 immature values (40.0%).

Table III shows the value of the two methods as assessed by multiple parameters. The sensitivity, specificity, and predictive values for a positive and negative test were not appreciably different.

Comment

In 1967 Gluck et al.[1] measured the surface activity of acetone-precipitated and acetone-soluble lecithins. They showed that toward the end of gestation, the acetone-precipitated fraction exhibited "normal" surface activity, whereas the total lecithin and acetone soluble fraction did not. Subsequently it was shown that the percentage of dipalmitoyl lecithin was greater in the acetone precipitate than in the acetone supernatant.[9] It was concluded from these studies that the surface-active component was dipalmitoyl lecithin and that it was separated from the total lecithin fraction by acetone precipitation.

This concept has resulted in the historic emphasis that the measurement of saturated phosphatidylcholine provides the most accurate method for predicting respiratory distress syndrome. However, many of the detection techniques measuring only unsaturated lecithin have proved reliable.[5, 10-12] The ability to predict fetal pulmonary maturation from unsaturated lecithin is possible because like saturated lecithin, it increases with gestational age.[3, 13] Therefore the removal of unsaturated lecithin by acetone precipitation appears to be an unnecessary goal.

The solubility of lecithin in cold acetone as reviewed by Brown and Duck-Chong[14] is reported to be dependent on numerous factors including (1) the length of the fatty acid side chains and/or their degree of saturation, (2) the presence of other phospholipids, (3) the

concentration of phospholipids, (4) the time allowed for precipitation, (5) the temperature during precipitation and centrifugation, (6) the water content of acetone, and (7) the use of chloroform to moisten the dried lipid extract before the addition of acetone. Since ≥80% of sphingomyelin is precipitated by cold acetone whereas 60% to 90% of lecithin is precipitated,[15, 16] acetone precipitation should cause a decrease in the L/S ratio. These factors decrease precision of the test, complicate comparison of results between laboratories, and add additional performance time.

The results of this clinical study clearly demonstrate that the inclusion of acetone precipitation in the determination of the L/S ratio does not enhance the predictivity of the test for detection of the respiratory distress syndrome.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1986 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 154 (January-June) and Vol. 155 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Serum fructosamine: A screening test for diabetes in pregnancy

Alistair B. Roberts, M.D., and John R. Baker, M.B.
Auckland, New Zealand

Serum fructosamine levels were measured in 1200 pregnant women at different stages of gestation, 167 of them having a glucose tolerance test. There was a significant fall in fructosamine levels throughout pregnancy and details of normal values at different gestational stages are presented. A good correlation was found between fructosamine and glucose tolerance test ($r = 0.813$). Nine women had gestational diabetes diagnosed by glucose tolerance test and eight of those had a serum fructosamine level greater than the ninety-fifth percentile. This study confirms our previous findings that serum fructosamine may be a useful screening test for gestational diabetes. (Am J Obstet Gynecol 1986;154:1027-30.)

Key words: Fructosamine, diabetic pregnancy, screening test

Diagnosis of diabetes in pregnancy is difficult and has traditionally depended on an assessment of clinical risk with oral glucose tolerance testing in suspected cases. Results are unsatisfactory with detection of only 62% of cases at best.[1] Systematic screening by blood glucose measurement 1 hour after an oral glucose load detects 79% of diabetic pregnancies but is inconvenient and time-consuming for the patient and provides a high (13%) rate of false positive observations.[2]

We have recently shown that 85% of women with diabetes in pregnancy have higher levels of serum fructosamine than nondiabetic pregnant women, suggesting that fructosamine might be a useful screening test for gestational diabetes.[3] Fructosamine concentrations reflect blood glucose control during the previous 1 to 3 weeks[4] but do not change significantly from day to day, offering the convenience of random blood sampling.[5] Major practical advantages of the test include technical simplicity, automation, and reliable standards.[6]

This study was designed to investigate the association between fructosamine levels and gestational age and to assess the usefulness of fructosamine as a screening test in the clinical situation.

Patients and methods

Patients. The nonpregnant reference interval for serum fructosamine was determined in 3664 female volunteers aged <1 to 89 (median 23) years who participated in a community health survey. Fructosamine concentrations during pregnancy were measured in 1200 women aged 13 to 44 (median 23) years attending the antenatal clinic at National Women's Hospital, Auckland, New Zealand. Serum samples were collected for fructosamine analysis in conjunction with normal antenatal screening tests at booking and 28 and 36 weeks' gestation. Results were not reported to the clinical team. No women with known diabetes or previous gestational diabetes were included in this reference population.

One hundred sixty-seven pregnant patients selected on clinical grounds had a 100 gm 3-hour glucose tolerance test ordered by the clinician in charge. Plasma

*Diabetic fasting plasma glucose is >105 mg/dl (5.8 mmol/L).

†Nondiabetic fructosamine values at different gestational stages are shown in Table I.

glucose results were interpreted by means of O'Sullivan's criteria.[7]

Analytical techniques. Serum fructosamine concentrations[6] were determined with commercial reagents and an automated centrifugal analyzer (F. Hoffman-La Roche, Basel, Switzerland). Changes in the calibration of the fructosamine assay[6] have increased results by about 0.8 mmol/L compared with previously published values.[3-5] Plasma glucose was measured with a glucose oxidase electrode (Beckman Instruments, Fullerton, California). The between-batch imprecisions for fructosamine and glucose were 1.4% and 2.7%, respectively.

Statistical methods. We compared fructosamine concentrations at different gestational ages with the use of Tukey's multiple range test for comparison of intervals.[8] Statistical significance was determined by Student's *t* test for paired or unpaired data as appropriate.

Results

Nondiabetic values. The range of fructosamine results in 3664 nonpregnant female volunteers are presented in Fig. 1. There were no significant age-related changes ($p > 0.05$) during the second, third, and fourth decades. Fructosamine concentrations for the 1650 women aged 15 to 40 (median 26) years were therefore used to derive the nonpregnant reference interval (Table I). There was no significant difference ($p > 0.05$) between nonpregnant and pregnant values during the first trimester of pregnancy [mean first-trimester fructosamine = 2.46 ± 0.16 (SD) mmol/L]. However, significant differences ($p < 0.05$) were noted both between first- and second-trimester [mean second trimester fructosamine = 2.41 ± 0.14 (SD) mmol/L] and between second- and third-trimester [mean third-trimester fructosamine = 2.34 ± 0.14 (SD) mmol/L] results (Fig. 2). Fructosamine concentrations at different gestational stages are presented in Table I.

Table III. Correlation between maternal glucose tolerance test results and serum fructosamine concentration in 167 pregnant women

Observations (n)	*Time between tests (wk)*	*Correlation coefficient*	
		Fasting glucose	*Area under curve*
30	<2	0.81	0.77
45	<3	0.79	0.74
63	<4	0.75	0.70
85	<5	0.64	0.60
111	<6	0.54	0.45
123	<7	0.54	0.43
139	<8	0.48	0.34
167	8+	0.42	0.24

All significant at $p < 0.001$

Comparison with glucose tolerance test. Diabetes was confirmed in nine of the 167 pregnant women who underwent a glucose tolerance test (prevalence 5.4%). Fructosamine measurements exceeded the ninety-fifth percentile for gestational age in eight of the nine individuals (Table II). A highly significant association ($p < 0.001$) was found between fructosamine levels and both fasting plasma glucose and area under the glucose tolerance curve (Table III). This association improved with decreasing time between fructosamine measurement and the glucose tolerance test.

Performance of fructosamine as a screening test. Predictive value of fructosamine screening tests are influenced both by the time between screening and positive glucose tolerance test and by the prevalence of diabetes in different subgroups. Nevertheless, our results suggest an optimal interval of 4 weeks between tests with six true positive, one false negative, and three false positive observations in the 63 women whose fructosamine level was measured during the 4 weeks preceding or after glucose tolerance testing (Table IV). Sensitivity, specificity, predictive value positive, and predictive value negative calculated for these 63 patients were 86%, 95%, 66%, and 98%, respectively.

Comment

Compared with nonpregnant values, maternal fructosamine concentration begins to fall in the second trimester of pregnancy and remains reduced until the end of pregnancy (Table I). Most of the change is presumably due to the fall in fasting or basal glucose concentrations, which occurs early in the first trimester.[9] Serum total protein and albumin concentrations also fall after the first 3 months of pregnancy[10] and may contribute to this 6.1% reduction of fructosamine level. Nevertheless, a group-specific reference range is required since correction for individual serum total protein and albumin concentrations is not beneficial.[5]

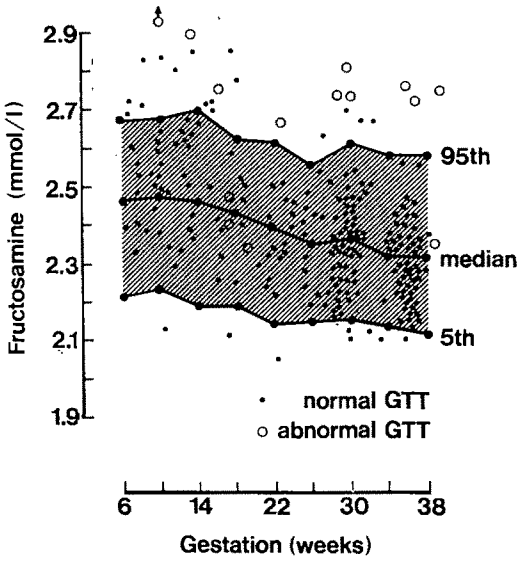

Fig. 2. Relationship between serum fructosamine and gestational age in 1200 pregnant women. *Hatched area* is the reference interval. Results from 167 patients who had oral glucose tolerance testing are superimposed.

Glucose intolerance may develop at any stage of pregnancy and must necessarily precede an elevation of serum fructosamine concentration. Fructosamines are formed by the nonenzymatic glycosylation of serum proteins.[6] The Amadori rearrangement reaction is rate-limiting and imposes a delay before changes in glycemia are reflected in the fructosamine result.[11] This concept is supported by our findings in the current study. We observed a highly significant correlation between maternal fructosamine and both fasting plasma glucose ($r = 0.81$) and area under the curve ($r = 0.76$) that was maximal after a lag period of 2 weeks (Table III).

Clinical application of fructosamine as a screening test for diabetes in pregnancy therefore requires discrimination values that are both adjusted for gestational age and designed to compensate for the rate of glycosylation of serum proteins. We chose the ninety-fifth percentile as our discrimination value but expect a false positive rate of <5% since the incidence of gestational diabetes in our clinic population is probably 4% to 5%.[12]

Overall sensitivity (86%) and specificity (95%) of the test compared favorably with those of other diabetic screening procedures[1,2] and detected eight of the nine new cases of diabetes (Table II). However, glucose tolerance tests in this study were only performed on a "high-risk" subgroup with a higher prevalence of gestational diabetes than in the general population. Because the positive and negative predictive values of screening tests are influenced by the prevalence of diabetes in the population, these figures may overestimate the performance of the fructosamine assay.

The cases of gestational diabetes in the current study

Table IV. Predictive value of fructosamine screening tests for gestational diabetes

n	*Time between GTT and fructosamine (wk)*	*Prevalence**	*Sensitivity*	*Specificity*	*Predictive value*	
					Positive	*Negative*
30	<2	16.6	0.80	0.92	0.66	0.96
63	<4	11.1	0.86	0.95	0.66	0.98
139	<8	6.5	0.89	0.88	0.35	0.99
167	8+	5.4	0.89	0.90	0.35	0.99

Diagnosis of gestational diabetes, based on a 100 gm oral glucose tolerance test (GTT) interpreted according to O'Sullivan's criteria.[7]

*Refers to the number of gestational diabetic patients in each subgroup.

were also relatively severe, with seven of the nine patients having fasting glucose levels >105 mg/dl (5.8 mmol/L). Indeed, six of the nine individuals had fasting plasma glucose levels >120 mg/dl, the threshold for diagnosing diabetes in a nonpregnant individual. This study does not determine whether fructosamine is sensitive enough to detect gestational diabetes with less severe glucose intolerance and particularly those cases where patients have normal fasting plasma glucose concentrations. Nevertheless, fructosamine would have detected 84 (90%) of the 93 cases of gestational diabetes diagnosed in this unit during the past 3 years.

The single patient with false negative fructosamine results (Patient 9, Table II) had definite gestational diabetes with a fasting plasma glucose level of 112 mg/dl (6.2 mmol/L) at 37 weeks and was delivered of a macrosomic infant (birth weight 4440 gm). We have observed similar false negative fructosamine results in a number of other women with gross maternal obesity and suspect interference in the assay from maternal hypertriglyceridemia.[6] Inspection of the sample before analysis for gross lipemia could prevent this problem.

In our initial report we advocated fructosamine measurement at 28 to 30 weeks' gestation.[3] Since case detection is improved by repeated sampling throughout pregnancy (Table II) at little extra cost or inconvenience to the patient, we now recommend routine serum fructosamine measurement at intervals of 4 to 6 weeks during pregnancy. Our results suggest that fructosamine estimation may be a simple and effective screening test for gestational diabetes.

Should the fifty-gram, one-hour plasma glucose screening test for gestational diabetes be administered in the fasting or fed state?

Donald R. Coustan, M.D., John A. Widness, M.D., Marshall W. Carpenter, M.D., Lee Rotondo, R.N., Doreen Chin Pratt, R.D. and William Oh, M.D.

Providence, Rhode Island

To determine whether the 50 gm, 1-hour plasma glucose screening test for gestational diabetes should be administered in the fasted or fed state, 50 presumed normal and 20 gestational diabetic pregnant women in the early third trimester underwent this test twice, once under each condition, within a 1-week interval. There was no difference in test results under the two conditions among the normal individuals (fasted 118.4 ± 24.7 mg/dl; fed 115.8 ± 23.4 mg/dl). However, when the test was administered to women with known gestational diabetes, the result was significantly ($p = 0.011$) higher if patients were fasted (173.9 ± 28.8 mg/dl) than if they had been given a standard 600 kcal meal 1 hour previously (154.8 ± 24.1 mg/dl). The effect of these two conditions on the sensitivity and specificity of the screening test is described, and it is suggested that the threshold for glucose tolerance testing be 130 mg/dl if the test is administered in the fed state. (Am J Obstet Gynecol 1986;154:1031-5.)

Key words: Gestational diabetes, diabetes screening test, diabetes and pregnancy; glucose tolerance test

The Second International Workshop-Conference on Gestational Diabetes Mellitus* has recommended that "*all* pregnant women should be screened for glucose intolerance since selective screening based on clinical attributes or past obstetric history has been shown to be inadequate. Screening should be by glucose measurement in blood." It was recommended that a 50 gm oral glucose screening test be performed at 24 to 28 weeks of pregnancy, ". . . given without regard to time of the last meal or the time of day."[1] When this 50 gm glucose screening test was described by O'Sullivan et al.,[2] it was similarly given without stipulation as to fasting or fed state.

In the report of O'Sullivan et al.[2] on the 50 gm screening test, glucose was measured in whole blood by the Somogyi-Nelson technique. A threshold of 130 mg/dl yielded a sensitivity of 79% and specificity of 87% for detecting gestational diabetes. With the change from whole blood to plasma measurements in most laboratories, and with current more specific methods of glucose measurement, varying recommendations for the appropriate threshold have been made, ranging from 135 mg/dl[3] to 150 mg/dl.[4] Our group has published data suggesting that a threshold of 135 mg/dl would be more sensitive, with use of data collected on individuals who took the test in the fasting state.[3] It seems reasonable to predict that the fasting individual might respond to a glucose load in a quantitatively different manner than would an individual in the fed state. The induction of a state of accelerated starvation by pregnancy, with insulin resistance, has been documented.[5,6] After a mixed meal, insulin and glucagon are secreted, and these hormones might alter the response to a subsequent glucose challenge. It might be expected that the previous ingestion of a mixed meal would blunt the response to a glucose challenge. On the other hand, after a meal is ingested, circulating glucose increases, so that a glucose load superimposed on this already increased plasma glucose level might result in a higher screening test value compared to that obtained in the fasting state.

The present study was designed to test the hypothesis that the ingestion of a standard mixed nutrient meal 1 hour before testing, as compared to the fasting state, would significantly change the response to the 50 gm

oral glucose screening test in normal pregnant individuals and in women with gestational diabetes.

Material and methods

The subjects of this study included 50 presumed normal pregnant women about to undergo screening for gestational diabetes and an additional 20 women already diagnosed as having gestational diabetes by the criteria of O'Sullivan and Mahan,[7] as modified by Carpenter and Coustan.[8] Both groups of subjects were recruited from private obstetricians' offices and clinics, affiliated with the Women and Infants Hospital of Rhode Island. The subjects were between 25 and 33 weeks of gestation at the time of study. Women with gestational diabetes had not yet started on their dietary regimen. No patient was receiving insulin, either therapeutically or prophylactically, at the time of study. Demographic data describing these 70 individuals are presented in Table I.

The experimental protocol was approved by the Research and Human Subjects Committee of the Women and Infants Hospital of Rhode Island. All subjects fasted overnight before reporting for study. Twenty-four hour dietary recall forms revealed that all subjects had ingested a minimum of 200 gm of carbohydrate on the day before the study. By means of a table of random numbers, the subjects were assigned one of two test schedules (Fig. 1). Subjects assigned to schedule A underwent the 50 gm glucose screening test in the fasting state, whereas those in schedule B did so in the fed state. For schedule A a fasting plasma glucose sample was first drawn, and then subjects drank a 50 gm oral glucose load (Limeondex, Curtin Matheson Scientific, Inc., Houston, Texas) over 5 minutes. Plasma glucose was again measured 1 hour later. For schedule B the subjects also had a fasting plasma glucose sample drawn but then consumed a standard mixed breakfast, consisting of approximately 600 kcal made up of approximately 52 gm of carbohydrate, 28 gm of protein, and 31 gm of fat. One hour after completion of the mixed meal, a 50 gm oral glucose load was ingested. A plasma glucose level was obtained 1 hour after ingestion of the glucose load. Within 1 week each subject was retested under the opposite conditions of her original test. The 50 presumed normal subjects and the 20 with gestational diabetes all completed the same protocol but were considered as two separate groups for purposes of randomization.

Blood samples were collected on ice in heparinized tubes, and centrifuged within 1 hour. Plasma glucose was determined with use of the glucose oxidase method (Yellow Springs Instrument Co., Yellow Springs, Ohio).

Presumed normal subjects were evaluated with a 100 gm, 3-hour oral glucose tolerance test if either screening test value exceeded or equaled 130 mg/dl. The criteria of O'Sullivan and Mahan,[7] as modified for plasma and glucose oxidase,[8] were used as the diagnostic standard for gestational diabetes. All subjects with known gestational diabetes had previously been diagnosed with such a test, and oral glucose tolerance tests were not repeated in this group.

Test results under the two conditions were compared with use of the *t* test for paired samples. Differences in screening test function under fasting and fed conditions were evaluated with use of Fisher's exact test.

Results

Table II depicts the mean plasma glucose results for the 50 presumed normal individuals who were screened. There was no significant difference between the fasting plasma glucose and 50 gm, 1-hour screening test values under the fasted and fed conditions. Among the 50 subjects there were four who met the criteria for gestational diabetes. Two had abnormal screening

Table II. Results of fasting and 50 gm, 1-hour screening tests in 50 presumed normal subjects

	Plasma glucose in 50 presumed normal subjects (n = 50) (mg/dl)		
	No-meal day (schedule A)	*Meal day (schedule B)*	*p*
Fasting	82.7 ± 7.6	82.1 ± 7.9	0.436
1 hour after 50 gm load	118.4 ± 24.7	115.8 ± 23.4	0.422

*Values expressed as mean ± SD.

Table III. Results of fasting and 50 gm, 1-hour screening tests in 20 previously diagnosed gestational diabetic subjects

	Plasma glucose in 20 gestational diabetic subjects (mg/dl)		
	No-meal day (schedule A)	*Meal day (schedule B)*	*p*
Fasting	95.3 ± 12.4	94.2 ± 10.2	0.628
1 hour after 50 gm load	173.9 ± 28.8	154.8 ± 24.1	0.011

Values expressed as mean ± SD.

tests in the fasted (160 and 146 mg/dl) but not the fed (119 and 118 mg/dl) state. Another had an abnormal result in the fed (132 mg/dl) but not the fasted (113 mg/dl) state. The fourth had an abnormal screening test under both conditions (158 and 167 mg/dl).

Table III depicts the plasma glucose values for the 20 subjects with known gestational diabetes. There was no difference in fasting values on the two testing days. However, there was a significant increase in the 50 gm, 1-hour screening test value when the test was administered in the fasted state, as compared to the fed state.

Table IV depicts the sensitivity of the 50 gm, 1-hour screening test when different thresholds were used and when the test was administered in either the fasted or fed state. The four subjects diagnosed as having gestational diabetes from among the 50 presumed normal individuals were added to the 20 known gestational diabetic patients for these calculations. The screening test was significantly more sensitive, at thresholds of 145 and 150 mg/dl, when administered in the fasted as compared to the fed state.

Table V depicts the specificity of the test in detecting normal individuals when different thresholds are used and when the test is administered in either the fasted or the fed state. There was no significant difference in specificity between the two conditions at any threshold evaluated.

To express the degree of glucose tolerance test abnormality in individual subjects, the sum of the amount

by which the two most abnormal values exceed the upper limits of normal[8] was calculated (ΔGTT). The mean ΔGTT for the 20 known gestational diabetic patients in this study was 51.4 (±47.0) mg/dl. The four subjects who were not detected under fed conditions at a threshold of 135 mg/dl had Δ scores of 15, 21, 20, and 26 mg/dl. The single subject who would have been missed with use of the same threshold under fasting conditions had a Δ score of 11 mg/dl. Thus these individuals had mildly abnormal glucose tolerance tests.

Comment

The function of a screening test is to provide a convenient, reliable, inexpensive, and safe means to choose individuals for further testing to detect a given disease state, in this case gestational diabetes. The 50 gm oral diabetes screening test has been shown to be inexpensive and reliable when compared to full 3-hour glucose tolerance testing of all patients meeting historic risk criteria.[2] Administration of the 50 gm glucose load in the fed state adds to the convenience of the test, ren-

dering unnecessary the scheduling in advance of the procedure and allowing immediate testing when the patient appears at an advanced state of pregnancy. No dietary preparation is required, which adds to patient acceptance. However, the results of the present study suggest that when the test is to be given in the fed state, a low enough threshold should be used to avoid missing a significant proportion of the individuals with gestational diabetes in the population. For example, if the test is administered 1 hour after a meal, a 140 mg/dl threshold will detect only 71% of patients with gestational diabetes and a 150 mg/dl threshold will detect only 46%. If the test is administered to fasting patients, however, 92% of gestational diabetic patients will be detected when the threshold is 140 mg/dl, and 83% when it is 150 mg/dl. These results are similar to those we have previously reported in which a threshold of 143 mg/dl yielded a sensitivity of 83% when the test was administered in the fasting state.[3]

It should be made clear that, given our study design, sensitivity calculations may overestimate the true sensitivity of the tests, since only those patients with plasma glucose levels >130 mg/dl underwent a 100 gm, 3-hour oral glucose tolerance test. Thus, if there are individuals within the population whose screening test values were <130 mg/dl, but who would have had an abnormal 3-hour oral glucose tolerance test had this been performed, they would be missed. Since most current recommendations are for the use of thresholds of >130 mg/dl, this fact only adds emphasis to the argument for a threshold of <140 to 150 mg/dl.

Because a standard mixed meal was used, the specific sensitivity and specificity calculations may not be applicable to glucose screening tests administered after the ingestion of unknown quantities and qualities of nutrients. Similarly, because a standard 1-hour interval was employed between the meal and the administration of the 50 gm glucose load, other intervals might yield differing results. The 1-hour time period was attractive because it was estimated that in the usual clinical situation, pregnant women eating a meal at home would be unlikely to appear for screening less than 1 hour later.

The 1-hour time period was also chosen because it was anticipated that the alteration in response to the glucose challenge would be greatest at this time (as compared to two or more hours). However, in a study of six nonpregnant type II diabetic individuals,[9] when 50 gm of glucose were ingested alone or in combination with 50 gm of protein, the plasma glucose level 1 hour later was the same under both conditions, but at over 4 hours the plasma glucose response was significantly lower when protein had been ingested than when the glucose was taken alone. Thus the direction of the effect reported herein is likely to be similar with other time intervals and other types of mixed meals. We hypothesize that the screening test value was lower when the test was administered in the fed state as compared to the fasting state because the previous ingestion of a mixed meal dampened the usual state of insulin resistance observed in fasting pregnant women.

Cheney et al.[10] have suggested that obese gestational diabetic patients manifest different degrees of glucose and insulin response to a mixed meal than do nonobese individuals. Our patient group contained only four obese gestational diabetic individuals, and their plasma glucose response to the glucose challenge under the two testing conditions did not differ qualitatively or quantitatively from those of the nonobese women with gestational diabetes, but no comment can be made about their response to the mixed meal itself.

Sensitivity and specificity can be calculated from the present study, since these test functions do not depend greatly on the prevalence of the disease in the population tested. However, it would be inappropriate to calculate the positive and negative predictive accuracy from our data, since these functions are largely dependent on disease prevalence. Our subjects are not a truly population-based sample, because the 50 women were recruited on the basis of their willingness to participate in the study. Since the study design was intended to test the hypothesis that the fasting or fed state of the individual has an impact on the results of the diabetes screening test and since each subject was used as her own control, the possibility of selection bias does not prejudice the results reported. This possibility does, however, preclude interpretation of the data in areas where prevalence is a critical factor.

Finally, it should be pointed out that data pertaining to the reproducibility of the 50 gm, 1-hour screening test are not available at present. A study in which the same subjects had the test performed under the same conditions on two or more occasions would be helpful.

It should be pointed out that of the 20 known gestational diabetic women recruited in the present study, eight (40%) had no known risk factors for gestational diabetes. This figure is remarkably similar to that reported by O'Sullivan et al.[2] in a population-based study and reaffirms the necessity to screen all pregnant women for this condition.

We conclude that the 50 gm, 1-hour diabetes screening test may be administered to pregnant women who are not fasting if a threshold of 130 mg/dl, and possibly 135 or 140 mg/dl, is used. However, if a higher threshold is to be used, patients should be tested in the fasting state to avoid missing the diagnosis of gestational diabetes in a significant number of individuals.

Decreased fetal cord prolactin concentration in diabetic pregnancies

Daniel H. Saltzman, M.D., Robert L. Barbieri, M.D., and Fredric D. Frigoletto, Jr., M.D.
Boston, Massachusetts

Infants of diabetic mothers are known to have a greater incidence of respiratory distress syndrome than normal control infants. Fetal lung maturation is modulated by a large number of hormones. To further investigate a possible role of hormonal modulators of lung maturation in infants of diabetic mothers, fetal cord prolactin, estrone, estradiol, thyroxine, triiodothyronine, and triiodothyronine-resin uptake index levels were measured in infants of diabetic mothers (n = 40) and nondiabetic mothers (n = 40) at term. Infants of diabetic mothers had significantly lower mixed-cord serum prolactin levels ($p < 0.0005$) than control infants. There was no significant difference in cord serum thyroxine, triiodothyronine-resin uptake index, triiodothyronine, estrone, or estradiol levels between the infants of diabetic mothers and the infants of control mothers. These findings raise the possibility that decreased fetal prolactin levels may be associated with, or contribute to, the delayed lung maturation reported with diabetic pregnancies. (AM J OBSTET GYNECOL 1986;154:1035-8.)

Key words: Diabetes, prolactin, pregnancy

The newborn respiratory distress syndrome contributes significantly to the increased neonatal morbidity and mortality seen in infants of diabetic mothers. Until 38.5 weeks' gestation, infants of diabetic mothers are at higher risk for respiratory distress syndrome than infants of nondiabetic mothers without perinatal disease.[1] Fetal lung maturation is modulated by a large number of hormones including insulin, cortisol, testosterone, estradiol, thyroxine, triiodothyronine, and prolactin.[2-4] The newborn infant of a diabetic mother is known to be in a hyperinsulinemic state that might delay lung maturation.[2] To further investigate possible hormonal effects on lung maturation in infants of diabetic mothers, fetal cord prolactin, estrone, estradiol, thyroxine, triiodothyronine-resin uptake index, and triiodothyronine levels were measured in infants of diabetic (n = 40) and nondiabetic mothers (n = 40) at term.

Material and methods

Forty-two consecutive insulin-requiring diabetic mothers with singleton pregnancies delivered by D. H. S. served as the experimental population. All mothers were cared for at the Joslin Clinic, Boston, Massachusetts, with use of previously published protocols.[5] Twenty-two male and twenty female infants were delivered. The last two male infants delivered were eliminated from the experimental group in order to balance group number. A reference group of 64 cord bloods obtained from normal parturients with no perinatal disease who delivered between 36 and 39 weeks' gestation served as the control pool. Controls were chosen from this pool in order to match infant sex, route of delivery, and gestational age (within 1 week) with the experimental group.

Serum prolactin, unconjugated estrone, estradiol, thyroxine, triiodothyronine-resin uptake, triiodothyronine, amniotic fluid lecithin/sphingomyelin ratio, and saturated phosphatidylcholine were measured as previously described.[6-8] Amniotic fluid was obtained by amniocentesis from all diabetic pregnancies within the 72 hours preceding delivery. Maternal hemoglobin A_1 was measured in the last trimester of pregnancy in all diabetic pregnancies. Maternal diabetes was classified according to the system of White.[9] Statistical analysis was performed with use of one-way and two-way analysis of variance.

Results

Gestational age at birth, birth weight, lecithin/sphingomyelin ratio, saturated phosphatidylcholine level, maternal age, White classification of maternal diabetes, and maternal hemoglobin A_1 levels in the third trimester are summarized in Tables I and II. The diabetic and control pregnancies were well matched for gestational age at birth. The infants of diabetic mothers had a significantly higher birth weight than the control infants ($p < 0.05$) (Table I).

Mixed-cord serum prolactin concentration was significantly lower in infants of diabetic mothers than in control infants ($p < 0.0005$) (Fig. 1). In the infants of diabetic mothers there was no significant correlation between cord prolactin concentration and amniotic fluid lecithin/sphingomyelin ratio or saturated phosphatidylcholine level. There was no significant difference in prolactin concentration between male and female infants (Fig. 1). There was no significant difference in mixed-cord serum levels of estrone or estradiol (Table III) or in mixed-cord serum concentration of thyroxine, triiodothyronine-resin uptake index, and total triiodothyronine between the infants of diabetic mothers and the control infants (Table IV). Levels of estradiol were significantly greater in male infants (controls plus infants of diabetic mothers) versus female infants (controls plus infants of diabetic mothers) ($p < 0.05$) (Table III).

Comment

In pregnancy three separate prolactin compartments are present. Maternal circulating prolactin is controlled by the maternal pituitary. Amniotic fluid prolactin is probably regulated by the decidua and membranes, while fetal prolactin is controlled by the fetal pituitary. Luciano and Varner[10] have reported that amniotic fluid prolactin concentrations in infants of diabetic mothers are the same as in nondiabetic controls. In this study we demonstrate that fetal mixed-cord prolactin concentrations are significantly decreased at term in infants of diabetic mothers.

The decreased levels of prolactin noted in the infants of diabetic mothers may result in delayed lung matu-

ration. Laboratory and clinical studies suggest that fetal prolactin may play an important role in lung maturation. Fetal levels of prolactin rise markedly during the third trimester of gestation, coincident with increased production of surfactant.[11] Hamosh and Hamosh[12] have reported enhanced synthesis of phospholipids in fetal rabbits after treatment with prolactin, suggesting that prolactin may be important in regulating lung maturation.[12] Additional circumstantial evidence exists which suggests that prolactin may play a significant role in fetal lung maturation. This includes the fact that the incidence of respiratory distress syndrome has been shown to be significantly higher in premature infants with lower serum prolactin concentrations.[13] Additional support for this proposed action of prolactin is provided by the fact that the incidence of respiratory distress syndrome in premature infants born of heroin addicts is markedly reduced.[14] Opiates, for example, morphine, are potent stimuli for prolactin secretion.

Birth weight has been shown to correlate positively with prolactin concentration.[15] The mean birth weight of our infants of diabetic mothers was significantly higher than that of the controls. Therefore, based solely on these birth weight differences, we would have expected higher prolactin levels in the infants of diabetic mothers rather than the lower levels we observed. Estrogens stimulate the secretion of prolactin. No difference was observed in the levels of estradiol or estrone in infants of diabetic mothers compared to controls (Table III). Levels of estradiol were significantly greater in male infants (controls plus infants of diabetic mothers) versus female infants (controls plus infants of diabetic mothers). This finding has been previously reported by Penny et al.[16] These results suggest that differences in estradiol cannot account for the lower prolactin concentrations we observed in the infants of diabetic mothers.

There was no significant correlation between prolactin concentration and two biochemical parameters of fetal lung maturity, amniotic fluid lecithin/sphingomyelin ratio and saturated phosphatidylcholine level. Since all amniotic fluid samples were obtained at term, it is likely that the critical period (?28-34 weeks) during which hormonal influences play a major role in lung maturation had passed. Measurement of prolactin in mixed cord serum from infants of diabetic mothers of <34 weeks' gestation would be the best way to address this issue. However, improvements in perinatal care, as well as our technologic inability to obtain routinely cord blood samples in utero, makes such a study currently unlikely.

The increased incidence of respiratory distress syndrome in infants of diabetic mothers has long been a major factor in the increased morbidity and mortality observed in pregnancies complicated by diabetes. The physiologic basis of this remains unknown. The inter-

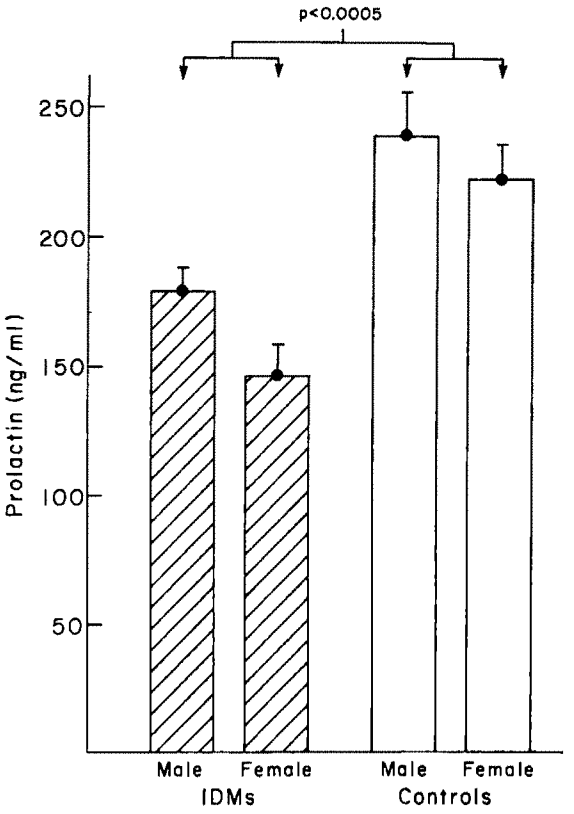

Fig. 1. Mixed-cord serum prolactin concentrations in infants of diabetic mothers *(IDMs)* and in control infants. (Mean ± SEM; n = 20 in each group.)

action of several hormones including prolactin may be a prerequisite to the normal development of the lung. Further study into the role of prolactin in lung maturation in diabetic pregnancies is warranted.

Boston, Massachusetts

Hyperplasia of testicular Leydig cells and ovarian theca-lutein cells is a common histologic finding in infants of diabetic mothers. The functional correlates of this histologic finding were investigated by measurement of the β-subunit of human chorionic gonadotropin, testosterone, dihydrotestosterone, androstenedione, estradiol, and estrone in the amniotic fluid compartment of gestations with male and female fetuses in diabetic mothers (N = 34) and control women (N = 34) at term. When compared with those of control subjects, gestations of diabetic mothers had significantly higher amniotic fluid concentrations of the β-subunit of human chorionic gonadotropin. Gestations with either male or female fetuses in diabetic mothers had significantly higher amniotic fluid testosterone and dihydrotestosterone levels when compared with those of their respective gender controls. In gestations with male fetuses in diabetic mothers there was a significant positive correlation between the β-subunit of human chorionic gonadotropin and testosterone. There was no significant difference in amniotic fluid androstenedione, estradiol, or estrone levels between the gestations of diabetic mothers and those of control women. These results suggest that the testicular Leydig cell and ovarian theca-lutein cell hyperplasia seen in infants of diabetic mothers is due, in part, to elevated levels of human chorionic gonadotropin and is associated with elevated testosterone and dihydrotestosterone concentrations in the amniotic fluid. (Am J Obstet Gynecol 1986;154:1039-43.)

Key words: Diabetes, β-hCG, androgens

Leydig cell hyperplasia is a common pathologic finding in male infants of diabetic mothers.[1, 2] In female infants of diabetic mothers, an increased number of ovarian theca-lutein cells has been reported.[1, 2] The functional correlates of these abnormal histologic findings were investigated by measuring the β-subunit of human chorionic gonadotropin (β-hCG), testosterone, dihydrotestosterone, androstenedione, estradiol, and estrone in the amniotic fluid of gestations of diabetic mothers at term. Normal parturient women undergoing amniocentesis at term before repeat cesarean section served as the control population.

Material and methods

Thirty-five consecutive insulin-requiring diabetic mothers with singleton pregnancies, who were delivered at Brigham and Women's Hospital, served as the experimental population. All mothers were cared for at the Joslin Clinic according to previously published protocols.[3] At 38 weeks' gestation the pregnant diabetic women underwent amniocentesis for measurement of the lecithin-sphingomyelin ratio (L/S ratio) and saturated phosphatidylcholine so that fetal lung maturity could be determined. For the diabetic women, gestational age was determined by the synthesis of menstrual dates, early sizing, and ultrasound examinations in the first and second trimesters. In the diabetic population 18 male and 17 female infants were delivered. The last male infant delivered was eliminated in order to balance group number.

The control population consisted of 36 women with normal pregnancies who planned to undergo repeat cesarean section. Because of unclear menstrual dates, lack of early prenatal care, and/or lack of early ultrasound dating, these women were scheduled for amniocentesis before delivery. Approximate gestational ages were estimated by synthesis of sizing at first prenatal

visit and earliest available ultrasound results. Nineteen female and 17 male infants were delivered. The last two female infants were eliminated in order to balance group number. All amniocenteses were performed under ultrasound guidance. For the experimental studies 4 ml of amniotic fluid was obtained. Sex assignments were determined at birth by an examination of the external genitalia.

Testosterone, dihydrotestosterone, androstenedione, estradiol, and estrone were measured as previously described.[4, 5] In brief, 3 ml of amniotic fluid was centrifuged at 1000 × g for 20 minutes to remove particulate and cellular debris. The supernatant was serially extracted with hexane. The steroids in the hexane extract were fractionated by Celite chromatography. Steroids were measured by radioimmunoassay with the use of specific antibodies. Tritiated steroids purified by Celite chromatography were added to the samples before extraction in order to assess recovery. Recoveries ranged from 70% to 95%. Results were scaled for recovery losses.

Amniotic fluid β-hCG was measured with the use of a double-antibody method as previously described.[6] A highly specific anti–β-hCG antibody was obtained from Serono (Braintree, Massachusetts). Human chorionic gonadotropin (hCG) (second international reference preparation) was used as the reference preparation. hCG (Cr-121) was used for iodination. The hCG was provided by the National Hormone and Pituitary Program.

The amniotic fluid L/S ratio and saturated phosphatidylcholine were measured as previously described. Maternal hemoglobin A_1 was measured in the last trimester of pregnancy in all the diabetic pregnancies. Maternal diabetes was classified according to the system of White. Statistical analysis was performed by the use of one-way analysis of variance.

Results

Gestational age at amniocentesis was significantly lower ($p < 0.05$) in the gestations of diabetic mothers (male fetuses, 38.1 ± 0.77 weeks; female fetuses, 38.0 ± 0.56 weeks; mean ± SD, N = 17 for each group) than in the control gestations (male fetuses,

*$p < 0.006$.
†No significant difference between groups.
‡$p < 0.05$.

38.9 ± 0.81 weeks; female fetuses, 38.6 ± 0.77 weeks). The range of gestational age at amniocentesis for the diabetic and control pregnancies was 36.7 to 40 and 38 to 40 weeks, respectively. Since the control pregnancies were composed of a group of women with uncertain menstrual dates and/or a late first prenatal visit the accuracy of the gestational age determination is difficult to assess. There was no significant correlation ($p > 0.05$) between gestational age at amniocentesis and β-hCG, testosterone, dihydrotestosterone, androstenedione, estradiol, or estrone levels in any group.

Birth weight was not significantly different ($p > 0.05$) between the infants of diabetic mothers (male, 3675 ± 559 gm; female, 3343 ± 510 gm; mean ± SD, N = 17 for each group) and the infants of control mothers (male, 3564 ± 332 gm; female, 3202 ± 372 gm). There was no statistically significant difference in the amniotic fluid L/S ratio between the diabetic gestations (male, 3.9 ± 1.17; female, 4.2 ± 1.90; mean ± SD, N = 17 for each group) and the control gestations (male, 4.7 ± 1.53; female, 4.1 ± 1.71). Similarly, there was no statistically significant difference in the amniotic fluid saturated phosphatidylcholine concentrations between the diabetic gestations (male, 1544 ± 434 μg/dl; female, 1487 ± 448 μg/dl; mean ± SD, N = 17) and the control gestations (male, 1490 ± 441 μg/dl; female, 1180 ± 538 μg/dl).

In the third trimester of pregnancy, maternal serum hemoglobin A_1 was 7.5% ± 1.4% (mean ± SD) in the diabetic mothers with male fetuses and 7.1% ± 1.1% (mean ± SD) in the diabetic mothers with female fetuses. The distribution of the diabetic mothers in the White classification was: gestational, four; Class B, 12; Class C, four; Class D, 11; and Class F to R, three.

The amniotic fluid β-hCG level was significantly higher in the diabetic gestations than in the control gestations ($p < 0.0001$) (Fig. 1). Analysis of relevant subgroups revealed that gestations with male fetuses in diabetic mothers had significantly higher amniotic fluid β-hCG levels than gestations with male fetuses in control mothers ($p < 0.0001$). Gestations with female fetuses in diabetic mothers had significantly higher amniotic fluid β-hCG levels than gestations with female fetuses in control mothers ($p < 0.0003$).

Gestations with male fetuses in diabetic mothers had significantly higher amniotic fluid testosterone levels than gestations with male fetuses in control mothers ($p < 0.001$) (Fig. 2). Gestations with female fetuses in diabetic mothers had significantly higher amniotic fluid testosterone levels than gestations with female fetuses in control mothers ($p < 0.005$). Amniotic fluid testosterone levels were similar in gestations with female fetuses in diabetic mothers and gestations with male fetuses in control mothers ($F = 0.60$, NS).

Amniotic fluid dihydrotestosterone concentrations were significantly higher in gestations with male fetuses ($p < 0.006$) and female fetuses ($p < 0.05$) in diabetic mothers when compared with levels in their respective gender controls (Table I). Amniotic fluid dihydrotestosterone concentrations were similar in gestations with female fetuses in diabetic mothers and gestations with male fetuses in control mothers ($F = 0.004$, NS).

In the gestations with male fetuses in diabetic mothers there was a statistically significant positive correlation between the amniotic fluid concentration of β-hCG and both testosterone ($r = 0.473$, $p < 0.05$) and dihydrotestosterone ($r = 0.585$, $p < 0.01$). In gestations with female fetuses in diabetic mothers and in control gestations (both male and female fetuses) there was no significant correlation between levels of β-hCG and testosterone or dihydrotestosterone. In the gestations with male and female fetuses in diabetic mothers there was no significant correlation between amniotic fluid concentrations of β-hCG, testosterone, or dihydrotestosterone and maternal insulin requirements, class of diabetes, or hemoglobin A_1 in the third trimester. In the gestations with male fetuses in diabetic mothers there was a significant correlation between birth weight and β-hCG ($r = 0.51$, $p < 0.05$), but in the gestations with female fetuses in diabetic mothers there was no sig-

nificant correlation between birth weight and β-hCG level.

Gestations of diabetic mothers and control gestations had similar amniotic fluid concentrations of androstenedione, estradiol, and estrone (Table I).

Comment

The results presented here demonstrate that β-hCG, testosterone, and dihydrotestosterone concentrations are significantly elevated in the amniotic fluid of gestations with both male and female fetuses in diabetic mothers at term as compared with those of appropriate gender controls. These differences must be interpreted with caution since the control and diabetic populations may differ by factors other than the diabetic state. For example, the control patients required amniocentesis before repeat cesarean delivery because of uncertain menstrual dates and/or late first prenatal visit. These control patients may differ significantly from the diabetic patients with respect to socioeconomic class, nutritional factors, or other characteristics. The impact of these possible differences was not evaluated in the current study.

The sources of amniotic fluid testosterone are poorly characterized, but in gestations with male fetuses a major source of amniotic fluid testosterone is probably urinary excretion of testosterone derived from the fetal testes.[7] The observation that gestations with male fetuses in diabetic mothers have elevated amniotic fluid testosterone concentrations correlates well with the pathologic observation that male infants of diabetic mothers have Leydig cell hyperplasia.[1] Hultquist and Olding[1] reported that quantitative histologic examination of the testes of male infants of diabetic mothers revealed a fourfold increase in Leydig cells per unit volume of testicular tissue when compared with the testes of infants of nondiabetic mothers.[1] In the Hultquist and Olding study[1] the total testicular weight was equivalent in the infants of diabetic and nondiabetic mothers. This finding supports the hypothesis that in male infants of diabetic mothers Leydig cell hyperplasia does not represent "nonspecific" organomegaly.

The stimuli that induce Leydig cell hyperplasia and increased amniotic fluid testosterone in gestations with male fetuses in diabetic mothers are not clear. However, both hCG[8] and insulin[9] may participate in this process. The amniotic fluid β-hCG concentrations measured in this study reflect both intact hCG and free β-hCG. At term, intact hCG is present in amniotic fluid at concentrations that are significantly higher than those of free β-hCG. Therefore, the β-hCG concentrations measured in this study probably reflect, in large measure, intact circulating hCG. The significant correlation between β-hCG and amniotic fluid testosterone supports the hypothesis that the Leydig cell hyperplasia is caused by elevated biologically active hCG. Insulin may also play a role in the pathogenesis of the Leydig cell hyperplasia of male infants of diabetic mothers. Gestations of diabetic mothers are characterized by hyperinsulinemia in the fetal compartment, and recent evidence suggests that insulin may directly stimulate Leydig cell growth and steroidogenesis.[9]

The normal human fetal ovary is not as steroidogenically active as the fetal testis.[7] However, in female infants of diabetic mothers ovarian theca-lutein hyperplasia has been observed.[1] This pathologic observation correlates well with the functional observation that amniotic fluid testosterone and dihydrotestosterone levels are elevated in female gestations of diabetic mothers. Both hCG and insulin[10] may participate in the ovarian theca-lutein hyperplasia. The presence of ovarian theca-lutein hyperplasia in female infants of diabetic mothers may have implications for the adult ovarian functions. It is conceivable that when these infants become adults the perinatal ovarian theca-lutein hyperplasia might result in a greater incidence of anovulation and ovarian hyperandrogenism as compared with that in control women.

The mechanisms that result in increased amniotic fluid β-hCG levels in gestations of diabetic mothers at term are unknown. Possible mechanisms include abnormalities in hCG production or metabolism or a disruption in the processes that maintain the high maternal to amniotic fluid hCG gradient (100 to 1). Diabetic pregnancies are known to be associated with hyperplacentosis.[2] Placental weight was not measured in this study, and therefore it is not possible to evaluate hyperplacentosis as a cause of elevated amniotic fluid β-hCG levels. However, birth weight correlates with placental weight, and in this study there was a significant correlation between birth weight and amniotic fluid β-hCG level in the male fetus ($r = 0.51$, $p < 0.05$) but not in the female fetus ($r = 0.08$ NS) in gestations of diabetic mothers. This would suggest that at least in gestations with female fetuses in diabetic mothers the elevated amniotic fluid β-hCG level is not due to macrosomia.

Other investigators have reported that amniotic fluid and maternal hCG levels are significantly elevated at term in pregnancies complicated by pregnancy-induced hypertension.[11] In our study, diabetic pregnancies complicated by pregnancy-induced hypertension (diagnosed by lateral recumbent diastolic blood pressure >90 mm Hg with no prepregnancy or postpartum evidence of hypertension) had higher amniotic fluid β-hCG concentrations (982 ± 187 mIU/ml, mean ± SEM, $n = 11$) than diabetic pregnancies not complicated by pregnancy-induced hypertension (516 ± 97.4 mIU/ml, $n = 23$, $p < 0.03$). However, the diabetic pregnancies not complicated by pregnancy-in-

duced hypertension also had significantly greater amniotic fluid β-hCG levels than those of normal control pregnancies (516 ± 97.4 versus 166 ± 41.7 mIU/ml, $p < 0.0001$). Therefore, pregnancy-induced hypertension and maternal diabetes are probably independent but interacting causes of elevated β-hCG at term.

The physiologic implications of elevated amniotic fluid testosterone and dihydrotestosterone concentrations in gestations of diabetic mothers are not clear. However, normal fetal lung maturation is dependent on the fetal concentration of a large number of hormones: insulin, cortisol, testosterone, prolactin, thyroxine, and estradiol.[12] At any given gestational age significantly more male infants have respiratory distress syndrome than female infants.[13] There is substantial evidence that this sex difference in lung maturity is due in part to differences in circulating androgens.[14] Elevated androgens in male and female fetuses of diabetic mothers may slow the rate of lung maturation in these fetuses and contribute to the observed increase in respiratory distress syndrome in infants of diabetic mothers.[15, 16]

In summary, elevated levels of hCG in diabetic pregnancies may contribute to testicular Leydig cell and ovarian theca-lutein cell hyperplasia. These structural abnormalities are paralleled by the functional observation that amniotic fluid testosterone and dihydrotestosterone concentrations are elevated in gestations of diabetic mothers.

Hypertensive diseases of pregnancy and parity

Norbert Gleicher, M.D., Leo R. Boler, Jr., M.D., Marija Norusis, Ph.D., and Alfonso Del Granado, M.D.

Chicago, Illinois

Chesley's classic long-term follow up study of eclamptic women clearly demonstrated the prognostic significance of parity in the differential diagnosis of various hypertensive diseases of pregnancy. Multiparous patients with eclampsia were different on long-term follow-up from primiparous eclamptic women. A logical conclusion from this observation is that multiparous and primiparous patient groups should be analyzed separately whenever hypertensive diseases of pregnancy are evaluated. This study is therefore an attempt to define the clinical profile of hypertension during pregnancy on the basis of parity alone. The prenatal and hospital records of 99 successive pregnant patients identified as hypertensive during a 1-year period at Mount Sinai Hospital Medical Center served as the study population. A group of 25 primiparous and 25 multiparous patients, all with uncomplicated pregnancies and normal deliveries in sequence during a 1-month period, served as normal nonhypertensive control groups. Various pregnancy parameters were statistically evaluated for study and control groups. Significant differences were found between hypertensive primiparous and multiparous patients in mean weight increase ($p < 0.05$), gestational age at first increase in blood pressure ($p < 0.007$), and time from first increase in blood pressure until delivery ($p < 0.008$). The difference in birth weight was not significant between hypertensive groups. In contrast, among the control groups, multiparous patients had significantly larger offspring than primiparous patients ($p < 0.01$). Weights of normal primiparous control women were almost identical to those of primiparous hypertensive women (3252.8 ± 511.8 versus 3203.26 ± 679.5 gm). Birth weights of offspring from multiparous hypertensive women, while not significantly different from those of primiparous hypertensive women, were significantly lower than those of multiparous control subjects (3093.94 ± 898.7 versus 3593 ± 305.6; $p < 0.01$). No significant differences in a variety of laboratory findings, reflexes, edema, or mode of delivery were observed between the various groups. The clinical and laboratory presentation of hypertension in pregnancy may be similar between primiparous and multiparous patients. Nevertheless, clear differences do exist in both maternal presentation and impact of maternal disease on fetal growth and development. These differences strongly suggest a different pathophysiology as the underlying cause of hypertensive disease in primiparous and multiparous pregnant women. Future studies of hypertensive diseases of pregnancy therefore need to be designed accordingly. (AM J OBSTET GYNECOL 1986;154:1044-9.)

Key words: Pregnancy hypertension, eclampsia, parity

Hypertensive diseases represent one of the most common among medical complications of pregnancy with a reported incidence of 6% to 30%.[1, 2] They also represent a major cause of maternal and fetal as well as neonatal morbidity and mortality.[2, 3] The literature abounds with studies devoted to the investigation of many different factors concerning cause, diagnosis, and management of hypertensive diseases in pregnancy.[4, 5] However, terminology as well as diagnostic criteria for various hypertensive diseases has remained vague and somewhat arbitrary in all systems of classification devised so far. It is particularly worrisome that most studies do not specifically refer to disease parameters in correlation with parity of investigated patient populations. This is despite Chesley's classic long-term follow-up study of eclamptic women, which clearly demonstrated the prognostic significance of parity in the differential diagnosis of various hypertensive diseases of pregnancy.[6] By prospective evaluation up to 1974 of 220 women who survived eclampsia between 1931 and 1951, Chesley was able to demonstrate the importance of parity in the differentiation between eclamptic patients and those he designated as having superimposed eclampsia. He chose to investigate eclamptic rather than preeclamptic patients because the diagnosis of eclampsia seemed more reliable than the diagnosis of the milder preeclampsia. Nevertheless, he recognized that even the diagnosis of eclampsia at times was made in error.[6] While the study was in progress, Chesley

noted that the majority of patients (75%) were primigravid and started a separate analysis of those patients from the remaining multigravid women. This then allowed him to demonstrate that the primigravid group of eclamptic patients and the control subjects had an equal chance to develop chronic hypertensive disorders on follow-up. In contradistinction, the multiparous group clearly demonstrated on follow-up an increased prevalence of underlying disease, which, in fact, led to a significant increase in remote deaths in this particular group as compared with both control subjects and primigravid eclamptic women.[6] Chesley himself rescinded a number of earlier publications based on these findings as he concluded that "any study of preeclampsia that includes multiparous patients will lead to erroneous conclusions."[6] Despite Chesley's general recognition as a pioneer in the investigation of hypertensive diseases in pregnancy, this recommendation has been largely ignored by the medical community. The issue is further complicated by the fact that since his recommendations were made some investigators have suggested that preeclampsia may occur in multigravid women if a new paternity has been established.[7] Such a contention would agree with the presently popular immunologic theory of preeclampsia[8] and may represent a factual finding; however, as the documentation lacks the sophistication of Chesley's study it should at this time not be taken as a reason to contradict his basic conclusions and recommendations.

Building on Chesley's observations we previously theorized that the underlying pathophysiology of pregnancy-related hypertension in primiparous patients may vary from that of multiparous patients.[8] In order to either support or refute such a concept the study presented here was designed to define hypertensive diseases of pregnancy solely on the basis of parity. Our observation of statistically significant differences between primiparous and multiparous hypertensive pregnancies in both mother and offspring supports the contention that differences in underlying mechanisms for the development of hypertension in both pregnant disease groups exist.

Material and methods

The prenatal and hospital records of 99 successive pregnant patients identified as hypertensive during a 1-year period at Mount Sinai Hospital Medical Center served as the study population.

Hypertension was defined as blood pressure ≥120/80 mm Hg during the midtrimester and 130/90 mm Hg in the last trimester of pregnancy. The Collaborative Perinatal Project[1] influenced the choosing of these

Table II. Type of delivery in primiparous and multiparous hypertensive patients

	Type of delivery			
	Primiparous		*Multiparous*	
	n	%	*n*	%
Normal spontaneous vaginal delivery	32	69.6	40	75.5
Cesarean section	14	30.4	13	24.5
Cephalopelvic disproportion	12	85.7	9	69.2
Fetal distress	2	14.2	4	30.8

$p = 0.66$ (χ^2 after Yates' correction).

values as cutoffs as it revealed that perinatal mortality varies with maternal blood pressure and begins to rise when the maternal diastolic pressure exceeds either 75 mm Hg in the second trimester or 85 mm Hg in the third trimester.

The hypertensive study population represented 7.2% of the total obstetric population delivered during that time period. A group of 25 primiparous and 25 multiparous patients, with uncomplicated pregnancies and normal deliveries in sequence during a 1-month period, served as normal nonhypertensive control groups.

Mount Sinai Hospital Medical Center is a tertiary care institution that serves a largely poor inner city population with above average high-risk characteristics. While approximately half of all obstetric patients are private and under the care of their own obstetricians, perinatal consultation is usually obtained in high-risk situations. The obstetric management of the study was therefore rather homogeneous.

All patient data were extrapolated by one of the authors (L. R. B.) while statistical evaluation was performed by a medical statistician (M. N.). Data were evaluated by appropriate methods, which included Student's *T* test, χ^2 after Yates' correction, and Mann-Whitney U–Wilcoxon rank sum W test.

Results

Hypertensive patients. Table I summarizes differences between primiparous and multiparous hypertensive patients.

Ninety-nine patients were identified as hypertensive; 53 were multiparous with a mean age of 27, and 46 were primiparous with a mean age of 18. The age difference was statistically significant ($p < 0.0005$) The mean weight increase during pregnancy in the multiparous hypertensive group was significantly lower than in the primiparous hypertensive group, 19.9 versus 24.4 pounds ($p < 0.05$).

The mean arterial pressure at the time of first blood pressure increase was almost equal for both groups, 103 for the multiparous group versus 102.6 for the primiparous group.

The mean gestational age at first increase in blood pressure was significantly different between the two groups: 31.4 weeks for multiparous hypertensive patients and 35.9 weeks for the primiparous group ($p < 0.007$).

The mean arterial pressure on admission for labor was not statistically different with the multiparous group having a value of 111.4 versus 113.2 for the primiparous patients.

The time from the first increase of mean blood pressure to delivery was 6.5 weeks for the multiparous group versus 2.1 weeks for the primiparous patients. This difference is statistically significant ($p < 0.008$).

A total of 75.5% of the multiparous hypertensive patients were delivered vaginally and 24.5% had cesarean section. Of these cesarean sections, four were secondary to fetal distress and the remainder were due to dystocia. Of the primiparous group 69.6% were delivered vaginally and 30.4% had cesarean section delivery. Two of these were secondary to fetal distress, and the remainder were for dystocia. The difference in delivery pattern between the two groups was not statistically significant ($p = 0.66$) (Table II).

The mean gestational age at the time of delivery was 37.5 weeks for the multiparous hypertensive patients and 37.9 weeks for the primiparous patients. Although the means were not significantly different between the groups a trend toward earlier birth of infants in the hypertensive multiparous group can be seen in Fig. 1.

The mean infant birth weights were not statistically different: 3093 gm in the hypertensive group versus 3203.3 gm for the primiparous patients. Multiparous patients, however, frequently had smaller infants (see Fig. 2). This observation is even further strengthened by the fact that in the multiparous group all infants >4000 gm were products of a pregnancy with gestational diabetes. There were no cases of gestational diabetes in the primiparous group. The relationship to birth weights of offspring of normal pregnancies is discussed below.

No significant abnormalities or differences in means for white blood cell count, hemoglobin/hematocrit, or platelets were observed in hypertensive patients. Uric acid levels were mildly increased in both hypertensive groups but were not statistically different from each other.

Reflexes and edema were reported equally in both hypertensive groups.

Normal control patients. Table I also summarizes data from 25 normal primiparous and 25 normal multiparous control patients. As may be seen, except for age and birth weight, no significant differences were

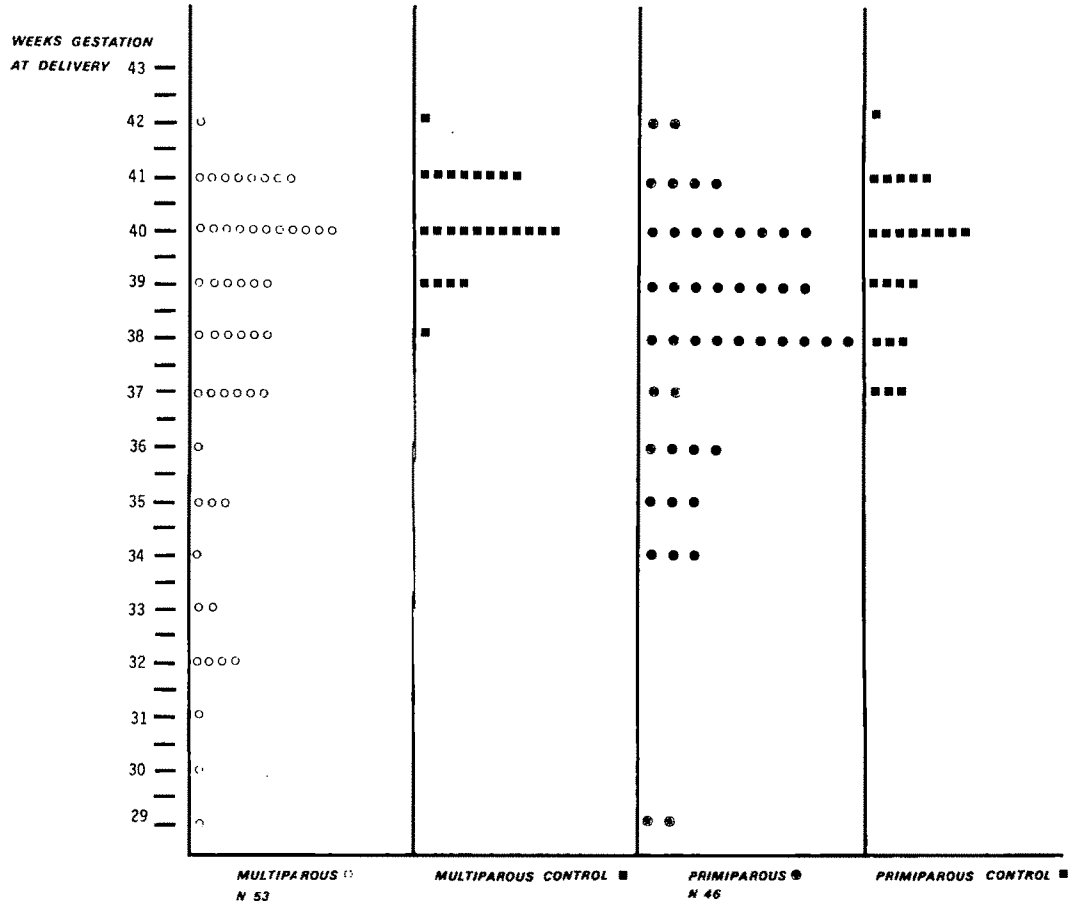

Fig. 1. Time of delivery for primiparous and multiparous hypertensive women and control patients. No statistically significant difference between groups was noted ($p = 0.50$, χ^2 after Yates' correction). A trend toward earlier delivery time for the multiparous hypertensive patients is seen.

noted between primiparous and multiparous healthy control women for gestational age at delivery, white blood cell count, hemoglobin/hematocrit, and platelet count.

Gestational age at delivery was lower in both primiparous and multiparous hypertensive patients than in normal control subjects. Primiparous hypertensive women were delivered of their infants statistically earlier than primiparous normal women at a mean gestational age of 37.9 ± 2.8 versus 39.5 ± 1.4 weeks, respectively ($p < 0.01$). Multiparous hypertensive women, who were not statistically different from primiparous hypertensive women, clearly were delivered of their infants earlier than their multiparous control counterparts (37.5 ± 3.4 versus 40.2 ± 0.4 weeks; $p < 0.001$).

Birth weights of offspring of normal multiparous women were, as expected, significantly higher than those of offspring of normal primiparous women (3593 ± 305.6 versus 3252.8 ± 511.8 gm; $p < 0.01$). Interestingly, birth weights of normal primiparous control subjects were almost identical to those of hypertensive primiparous women (3252.8 ± 511.8 versus 3203.3 ± 679.5 gm). Birth weights of offspring of hypertensive multiparous women, while not statistically different from those of offspring of hypertensive primiparous women, were however statistically clearly lower than those of offspring of multiparous control women (3093.9 ± 898.7 versus 3593 ± 305.6 gm; $p < 0.01$).

White blood cell counts and hemoglobin/hematocrit were not different in hypertensive and control patients. Platelets of both primiparous and multiparous hypertensive patients were, however, clearly lower than in their respective control subjects ($p < 0.02$ for primiparous groups; $p < 0.001$ for multiparous groups; Table I).

Comment

Mariceau's observation in 1694,[9] indicating that preeclampsia-eclampsia appeared primarily in primigravid women, is an observation that today we consider confirmed. It is indicative of our lack of progress in the

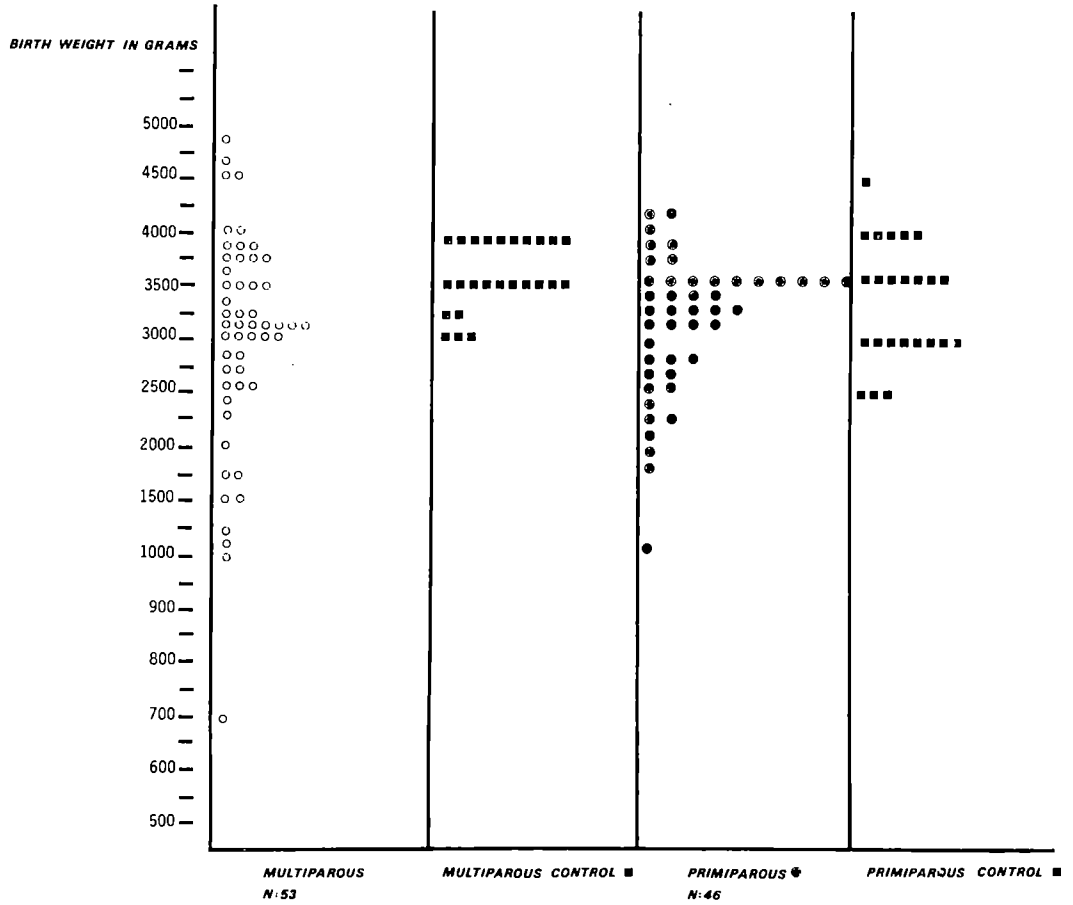

Fig. 2. Birth weights of infants from primiparous and multiparous hypertensive patients and control patients. While no statistical differences in means between groups was noted ($p = 0.45$, χ^2 after Yates' correction), multiparous control women showed the expected higher weight in comparison to that of primiparous control women while hypertensive multiparous pregnancies resulted in neonatal weights almost identical to those of multiparous pregnancies. Furthermore, all infants with weights >4000 gm born to multiparous mothers with hypertension came from pregnancies complicated by gestational diabetes while no patients in the primiparous hypertensive group had diabetes.

understanding of hypertension in pregnancy that, almost 300 years after Mariceau's observation, gravidity still represents the single best option in the differential diagnosis of hypertensive diseases during pregnancy.

The widely used term "superimposed" preeclampsia for a largely multiparous group of patients, in contrast to the overwhelmingly primiparous group of patients with "true" preeclampsia, suggests that the term preeclampsia is indicative of the same underlying pathophysiologic characteristics in either patient populations. If such a concept were to be correct then maternal clinical presentation and impact of maternal disease on pregnancy should be the same or at least very similar. The clinical difficulty in differentiating the various forms of hypertensive diseases in pregnancy has been the basis of much confusion. Considerable data, suggesting significant differences in both maternal and fetal presentation between primiparous and multiparous hypertensive pregnancies, have been recognized since Chesley's earliest studies. Chesley[10] himself noted that "superimposed" preeclampsia exhibited the most dangerous prognosis. Similarly, it has been known for at least a decade that offspring of "superimposed" hypertensive patients exhibit a considerably higher incidence of intrauterine growth retardation.[11] Clear differences in clinical presentation between primiparous and multiparous hypertensive pregnancies have thus been apparent for a considerable time. These differences, however, have been directly attributed to underlying medical conditions in the multiparous hypertensive group rather than to the underlying pathophysiologic characteristics that create hypertension in pregnancy.

By comparing primiparity to multiparity in a crossover analysis between hypertensive and normal pregnancies this study represents an attempt to control for the multiparity factor of underlying disease. If multiparity and automatically associated conditions such as

advanced maternal age are in fact responsible for the outcome differences between primiparous and multiparous hypertensive pregnancies then the crossover analysis for multiparous healthy control women should reveal some of these effects.

The study presented here, contrary to that supposition, very strongly supports the contention that different pathophysiologic mechanisms are operative in primiparous and multiparous hypertensive patients during pregnancy. While the clinical presentation at the time of the labor may in fact be very similar, as indicated by identical blood pressure elevations in labor, similar timing of delivery, and largely similar laboratory data (Table I), considerable differences in both maternal and fetal presentation were nevertheless noted. Multiparous patients exhibited a significantly earlier mean arterial pressure increase compared with that of primiparous patients ($p < 0.007$). Because the time of delivery for both hypertensive groups was almost identical, the time period between first mean arterial pressure rise and delivery was significantly longer in the multiparous group ($p < 0.008$). Maternal weight gain in the multiparous group was significantly lower ($p < 0.05$). Unfortunately, weight information was very incomplete in the two control groups and reliable weight data therefore could not be obtained for these patients.

The most convincing results from this study are those referring to fetal outcome. While the control populations are reflective of the known fact that birth weights increase with parity[12] this relationship was not observed between the two hypertensive groups. In fact, the multiparous hypertensive group had a lower (although not significant) mean birth weight than the primiparous group of hypertensive mothers. Moreover, while primiparous hypertensive women had only a 49 gm lower mean birth weight than primiparous normal control women, multiparous hypertensive women had newborn infants who were 500 gm lighter in weight than offspring of multiparous normal control mothers.

This finding is most remarkable since it suggests that the nutritional support to the fetus during multiparous hypertensive pregnancy is considerably diminished as compared with that during the primiparous gestation. Nutritional support to the fetus is largely dependent on vascular perfusion of the placenta and transmission of nutrients.[13] Growth-retarded infants are usually associated with growth-retarded, calcified, and insufficient placentas. Such placental pathologic conditions have been repeatedly reported in conjunction with superimposed multiparous hypertensive diseases.[10] In contrast, classical primiparous preeclampsia has been shown to be at least initially associated with larger than normal placentas.[14] The term hyperplacentosis has in fact been coined for conditions that are associated with larger than average placental volume, all of which are associated with a higher than normal incidence of preeclampsia/eclampsia.[15] By the time delivery occurs the initially abnormally large placentas have decreased in size, often to sizes even smaller than average.[15] Nevertheless, the classically growth-retarded placentas with calcifications and infarcts are not a usual feature of primiparous preeclampsia but are fairly typical of the multiparous form of hypertensive disease in pregnancy.

The causes and/or pathophysiologic features of preeclampsia/eclampsia are still only poorly understood. The study presented here suggests that, whatever the underlying mechanisms of maternal vascular disease may be, the resultant maternal and fetal effects vary between multiparous and primiparous hypertensive pregnancies. This observation needs to be considered in reference to terminology of hypertensive diseases in pregnancy as well as in the study design of future investigations of hypertension in pregnancy.

Predictive value of fibronectin levels in normotensive gravid women destined to become preeclamptic

John Lazarchick, M.D., Thomas M. Stubbs, M.D., Lydia Romein, B.A., J. Peter Van Dorsten, M.D., and C. Boyd Loadholt, Ph.D.
Charleston, South Carolina

The plasma fibronectin concentration was abnormally elevated (>400 μg/ml) in 16 of 17 normotensive gravid women who subsequently developed preeclampsia. Of this group, 13 had elevated levels detectable ≥4 weeks before the onset of hypertension. Our results indicate that plasma fibronectin levels can be abnormally increased long before the onset of clinical symptoms and that abnormalities of this glycoprotein may be an early indication of this pathologic process. (Am J Obstet Gynecol 1986;154:1050-2.)

Key words: Plasma fibronectin, preeclampsia, predictive value

The early suspicion of preeclampsia includes the clinical findings of abnormal edema and/or suspicious weight gain and therefore may require subjective interpretation. We have demonstrated in a previous study that plasma fibronectin concentrations are abnormally elevated in patients with preeclampsia and suggested that measurement of this glycoprotein may offer a biochemical marker for this disorder.[1] The present study was undertaken to determine the utility of plasma fibronectin levels as an indicator of normotensive gravid patients destined to become clinically preeclamptic later in pregnancy.

Material and methods

All obstetric outpatients seen at the Medical University of South Carolina routinely had blood drawn for determination of plasma fibronectin levels as part of their clinic visits. The plasma was frozen at −70° C and later assayed for plasma fibronectin as indicated. All assays were performed in a blinded fashion with the clinical diagnoses not being available to the physician performing the assay. Seventeen of these patients subsequently developed preeclampsia during the course of pregnancy. Twenty-three gravid patients with uncomplicated pregnancies were randomly selected as controls. The number of plasma samples available from any one patient varied and depended on the gestational age at which the patient was first seen in the outpatient clinic. Abnormal weight gain was defined as ≥5 pounds per week. Suspicious weight gain was defined as ≥2 pounds per week or ≥6 pounds per month. Edema was considered abnormal if described as such by the physician caring for the patient. Preeclampsia was defined by widely used criteria.[2] No patients with insulin-dependent diabetes mellitus or chronic hypertension were included in the study.

Blood samples of 10 ml were collected atraumatically by venipuncture with 21-gauge needles and transferred to test tubes containing sodium citrate anticoagulant. Platelet-poor plasma was prepared by centrifugation at 2100 × g for 15 minutes. Plasma fibronectin was measured as previously described.[1] Unless assayed that day, all samples were frozen at −70° C. This freeze-thaw step had no effect on the measurement of fibronectin concentration. Serial aliquots of an internal control plasma sample, which were thawed and assayed at weekly intervals, had a mean fibronectin concentration of 403 μg/ml ± 37 with a range of 375 to 420 μg/ml and a coefficient of variation of 4.5%. Results were analyzed with Student's *t* test.

Results

The results of the preeclamptic group in this study are shown in Table I. Seventeen patients had a diagnosis of preeclampsia made during the course of pregnancy. The mean (±SD) fibronectin concentration for this group was 597 ± 173 μg/ml. In 16 (94%) of these patients the fibronectin concentration was abnormally increased (>400 μg/ml) before the appearance of hypertension. Thirteen of these patients had elevated fibronectin levels detectable ≥4 weeks before the appearance of hypertension. In 12, the elevated fibronectin levels preceded abnormal or suspicious weight gain. Earlier fibronectin elevations cannot be ruled out in those patients who had infrequent sampling or a
